MEDICAL ENTOMOLOGIST, NYASLAND PROTECTORATE

In this preliminary communication it is not intended to review and discuss fully the immense literature on experimental and field observations regarding the direct transmission of trypanosomes, leishmania, and other blood-inhabiting organisms. It is proposed, however, to emphasize the important part which may be played by non-biting haematophagous flies in the mechanical dissemination of blood-inhabiting organisms, which appears hitherto to have been largely overlooked.

Most authorities are in agreement that, apart from cyclical transmission through the agency of tsetse flies, direct methods of infection by *Tabanidae*, *Stomoxys*, and other biting flies play an important part in the active spread of trypanosomiasis. Thus Duke (1919, 1921, 1923) believes that the sleeping sickness epidemics which sweep over certain parts of Africa are due to mechanical infection from man to man by tsetse flies; and Hornby (1921) states that the direct spread of trypanosomes among domestic stock is by no means uncommon as the result of the introduction of an infected animal into a clean herd living in a tsetse-free area. Wenyon (1926), in summing up the evidence on mechanical transmission, says it has been clearly demonstrated that a purely mechanical infection may occur by a biting fly contaminating the wound it inflicts with infective blood which it has recently taken into its proboscis from another host.

Earlier Observations on Fly Transmission

In proportion, however, to the amount of research that has been undertaken on direct transmission, the positive experimental evidence that has been brought forward incriminating these biting flies is so meagre as to suggest that the mechanism of this method of transmission is not fully understood. It was concluded so recently as 1933, at the conference at Entebbe on the tsetse and trypanosomiasis, that further information based on experimental work was necessary to elucidate the problem of mechanical transmission.

Work on the transmission of the tissue-inhabiting pathogenic protozoa by Diptera other than the biting species, *M. domestica* in particular, is on record, though the observations are scanty. Castellani (1907) fed *M. domestica* and allied species of flies on scrapings from yaws which contained *Treponema pertenue*, and afterwards, by transferring them to scarified sores on monkeys, produced an infection in one of the experimental animals. The flies were kept in position on the sores of the monkeys for two hours. Darling (1913) reported mechanical transmission of *T. evansi* (*T. hippicum*) to animals through the agency of house-flies which infested the open sores on mules in Panama. Laveran (1880) first suggested that oriental sore in Biskra might be due to transference of infection by flies, and Wenyon (1926) stated that it was highly probable that the house-fly, which swarms round

exposed oriental sores, especially in children, might sometimes carry the causative organism on its feet or proboscis to abrasions on the skin of another person. The same observer thought that leishmania bodies might pass rapidly through the gut of the fly and so be deposited with the dejecta.

Observations relating to non-biting hematophagous flies appear to be very few, probably from the fact that most observers have failed to distinguish the various species from *M. domestica*. It is apparent, however, from a study of their life-history and habits, that they are far more likely to be agents in the dissemination of blood-inhabiting protozoa than *M. domestica*. Patton recognized that the wounds produced by biting flies might be infected subsequently through the agency of non-biting blood-drinking muscids. His observations related to an Indian species named by Austen (1910) *M. pattoni*. Patton and Cragg also give a chapter on the hematophagous flies in their classical textbook, and emphasize their character and habits.

The Non-biting Muscid in Nyasa

In Nyasaland various species of these muscids abound, one in particular—*Musca spectanda* Wied—being, as recent work by W. A. Lamborn has shown, almost entirely dependent throughout its whole life on man. The eggs are laid solely on human excreta, on which the larvae feed to maturity. The adult flies, often in large numbers, especially in the early morning, settle on man, awaiting the opportunity to slake their thirst and deposit their eggs on his freshly excreted faeces. Swarms of non-biting hematophagous flies, including *M. spectanda*, may be found infesting abrasions and sores on domestic animals. They drink greedily the blood which oozes from the bites of *Fabianus*, *Stomoxys*, and other biting flies, and actually hustle them off in order to secure a meal. *M. spectanda* appears to be almost unique in the way in which it concentrates on man. It attacks persistently and with great determination scratches, wounds, open sores, tropical ulcers, yaw nodules, etc., and greedily drinks to repletion blood, serum, or secretions from the nose, eyes, or mouth. In one instance thirty-five *M. spectanda*, all females, were captured in three-quarters of an hour from a linear scab half an inch long on the dorsum of the foot of a native, when, despite the abundance of *M. domestica* in the neighbourhood, not a single specimen was included in the catch. Catches of fifty to sixty *M. spectanda* can be made readily within an hour in the early morning from the shoulders of any native.

These observations by Lamborn, and the hypothesis put forward by him (1932) concerning the part muscids may play in the spread, not only of trypanosomiasis, but also of cutaneous leishmaniasis, led to the experimental work described below, for which the senior author was largely responsible. As will be noted, the most important fact that has emerged is that this group of flies is capable of taking up and actively depositing blood-inhabiting protozoa and spirochaetes, either by regurgitating them from the proboscis or by passing them unchanged and alive in the excreta over a period of five to six hours.

Mechanical Transmission of *Trypanosoma brucei* through the Agency of *Musca spectanda*

In the experiments over 200 flies, both bred and wild, were used. The usual procedure was to feed them on blood excreta from a puncture of the ear of a dog or from the tail of a rat infected with *T. brucei*. A certain proportion of flies thus fed commenced in about five minutes to pass in their dejecta either pure blood or blood-stained food full of actively motile trypanosomes,

while some flies continued to pass, at intervals, living trypanosomes for a period of at least six hours after an infective feed. A smaller proportion of flies were seen to blow a blob of blood containing living trypanosomes from their proboscis five or ten minutes after a feed.

Blood-stained excreta and regurgitation of blood were observed not only in the case of the flies fed on infected blood but in those fed on the normal blood of man and domestic animals and on other fluid material. The blood-passing capacity of various batches varied to a very marked degree. This variation may be associated possibly with the food requirements necessary for the maturation of the ova in the female.

Thus in one experiment twelve flies were fed on a dog infected with *T. brucei*, and although numerous drops of clear excreta were passed over a period of five hours in no instance was either blood or trypanosomes detected. This batch of flies was killed after five hours, and motile trypanosomes were seen in the gut of eight of them.

In another experiment seven out of twelve of the flies fed on a dog infected with *T. brucei* commenced to pass drops of blood-stained excreta in from five to ten minutes, and continued to excrete numerous drops for five hours. All these drops contained active trypanosomes. One fly also regurgitated a drop of blood from its proboscis full of active trypanosomes.

Over a period of five hours one fly passed forty-one drops of dejecta, another seventeen drops, and a third fifty-three drops, all of which were blood-stained and contained living trypanosomes. As an example of the extraordinary capacity of this muscid to deposit living trypanosomes in its excreta it may be stated that a batch of ten, fed to repletion on the blood of a dog infected with *T. brucei*, passed in six hours 265 droplets stained with blood and containing living trypanosomes.

In carrying out experimental infections flies, after a feed on *T. brucei*, were placed in specimen tubes covered with gauze, and the drops of excreta containing living trypanosomes passed on to the sides of the tube were drawn up into a capillary in saline or citrate solution.

Into one rat excreta containing trypanosomes was introduced intraperitoneally, infection duly taking place. A second rat was successfully infected by placing a drop of excreta on a small fresh cut on the ear, and a third rat developed an infection with *T. brucei* after a drop of the fly's excreta had been placed on a drop of blood exuding from a fresh puncture made by a tabanid, *T. fisterius* Ric.

From the experimental observations here recorded there cannot be any doubt that, apart from any mechanical transmission by the action of biting flies *per se*, the combined action of these and the non-biting blood-drinking species is capable of bringing about the transmission of trypanosomes under natural conditions. The presence of hordes of these flies, which persistently infest and annoy both man and other animals—especially when abrasions or sores are present—is a significant fact when it is realized that their capacity for distributing viable trypanosomes is so perfect. Their predilection for the mucous surfaces, moreover, suggests a means whereby infection with trypanosomes may take place. Experimental work to test the possibility of infecting rats through the eye, nose, and mouth by the excreta of these flies containing *T. brucei* was, however, unsuccessful.

Passage of Living Leptomonads of the Cultural Forms of *Leishmania dorovarti*, *L. infantum*, and *L. tropica* through the Intestine of *Musca spectanda*

Observations on visceral leishmaniasis indicate that this form of the disease has the same geographical distribution as sandflies of the same group—*Phlebotomus argentipes* in India, *P. chinensis* in China, *P. perniciosus* in Italy,

paranoid trends. They include real cases of abnormal sexual incompatibility, ranging down to cases which have failed to adjust in regard to contraception, with fears of pregnancy, and menopausal cases, where one of the parties has ceased to desire sexual relations. An appreciation of this saves much investigation of elusive symptoms.

Coming to the special senses, blindness, deafness, and loss of speech may all occur. Elaborate tests to deceive the senses have been evolved to prove the functional nature of the cases. Unilateral blindness is perhaps more usual; conjunctivitis is not uncommon, being easy to produce and resulting in a similar incapacity. Aphonia, where phonation is lost but articulation is preserved, is the common hysterical lesion, as the patient can still converse in a whisper, again suffering incapacity without great inconvenience. The partially adducted state of the vocal cords is characteristic. The adoption of face-saving methods in inducing speech by faradism facilitates cure of this symptom.

Mutism is more generally a sign of stupor, although it may occur in persons fully alert mentally, but silent owing to hysterical or delusional ideas. Among the common causes of stupor may be mentioned post-epileptic phenomena, depressed cyclothymic cases, hysterics and schizophrenics, and cases of so-called idiopathic stupor. Somnolent cases of encephalitis lethargica may resemble this state, and cases of pathological somnolence or narcolepsy, some of which may be associated with organic lesions, such as cerebral tumour. Among the rarer conditions may be mentioned such a phenomenon as cataplexy, a condition in which movement is impossible, although consciousness is retained. While some of such cases have a physiological basis, many on investigation will be found to be cases of hysteria.

Without an adequate history, differentiation between the conditions may be difficult. The principal difficulty is in separating the cases of hysteria from the praecox syndrome. The hysterical type, fully alert to her surroundings, who, under suggestion or other suitable conditions, passes into a hysterical trance, is usually obvious, but when extended periods of stupor, with few if any remissions, occur, with marked dissociation, the fear will be that the case is one of serious schizophrenic dissociation, even when mannerisms and other suggestive schizophrenic symptoms are absent.

In conclusion, I would again repeat that neglect of the psychological aspect leads to failures in diagnosis and treatment, owing to undue emphasis being placed on the individual symptoms. When both physical and mental aspects are considered, a true perspective is obtained, with beneficial results both to doctor and to patient.

With the July issue of the *Fortschritte auf dem Gebiete der Röntgenstrahlen* began the fiftieth volume of a monthly periodical which has rendered very great services to radiology the world over. Founded in 1897 by Heinrich Albers-Schönberg, who was himself a radiological pioneer, it has given publicity to many of the outstanding discoveries in connexion with x rays, and been a foster father to various of the subsequent journals which dealt with the more specific applications of this subject as they came into being. It has been adopted as the official organ of radiological societies in Czechoslovakia, Austria, Hungary, and Russia, as well as in Germany, and has won universal recognition as a sound and reliable as well as a progressive periodical. It is only right that the July issue should begin with the first Albers-Schönberg memorial lecture, which was delivered at the congress of the German Radiological Society in Baden-Baden last April. The present editor is Professor Rudolf Grashey-Köln.

MECHANICAL TRANSMISSION OF TRYPANOSOMIASIS, LEISHMANIASIS, AND YAWS THROUGH THE AGENCY OF NON-BITING HAEMATOPHAGOUS FLIES

(PRELIMINARY NOTE ON EXPERIMENTS)

MEDICAL ENTOMOLOGIST, NYASALAND PROTECTORATE

In this preliminary communication it is not intended to review and discuss fully the immense literature on experimental and field observations regarding the direct transmission of trypanosomes, leishmania, and other blood-inhabiting organisms. It is proposed, however, to emphasize the important part which may be played by non-biting haematophagous flies in the mechanical dissemination of blood-inhabiting organisms, which appears hitherto to have been largely overlooked.

Most authorities are in agreement that, apart from cyclical transmission through the agency of tsetse flies, direct methods of infection by *Tabanidae*, *Stomoxys*, and other biting flies play an important part in the active spread of trypanosomiasis. Thus Duke (1919, 1921, 1923) believes that the sleeping sickness epidemics which sweep over certain parts of Africa are due to mechanical infection from man to man by tsetse flies; and Hornby (1921) states that the direct spread of trypanosomes among domestic stock is by no means uncommon as the result of the introduction of an infected animal into a clean herd living in a tsetse-free area. Wenyon (1926), in summing up the evidence on mechanical transmission, says it has been clearly demonstrated that a purely mechanical infection may occur by a biting fly contaminating the wound it inflicts with infective blood which it has recently taken into its proboscis from another host.

Earlier Observations on Fly Transmission

In proportion, however, to the amount of research that has been undertaken on direct transmission, the positive experimental evidence that has been brought forward incriminating these biting flies is so meagre as to suggest that the mechanism of this method of transmission is not fully understood. It was concluded so recently as 1933, at the conference at Entebbe on the tsetse and trypanosomiasis, that further information based on experimental work was necessary to elucidate the problem of mechanical transmission.

Work on the transmission of the tissue-inhabiting pathogenic protozoa by Diptera other than the biting species, *M. domestica* in particular, is on record, though the observations are scanty. Castellani (1907) fed *M. domestica* and allied species of flies on scrapings from yaws which contained *Treponema pertenue*, and afterwards, by transferring them to scarified sores on monkeys, produced an infection in one of the experimental animals. The flies were kept in position on the sores of the monkeys for two hours. Darling (1913) reported mechanical transmission of *T. evansi* (*T. hippicum*) to animals through the agency of house-flies which infested the open sores on mules in Panama. Laveran (1880) first suggested that oriental sore in Biskra might be due to transference of infection by flies, and Wenyon (1926) stated that it was highly probable that the house-fly, which swarms round

exposed oriental sores, especially in children, might sometimes carry the causative organism on its feet or proboscis to abrasions on the skin of another person. The same observer thought that leishmania bodies might pass rapidly through the gut of the fly and so be deposited with the dejecta.

Observations relating to non-biting haematophagous flies appear to be very few, probably from the fact that most observers have failed to distinguish the various species from *M. domestica*. It is apparent, however, from a study of their life-history and habits, that they are far more likely to be agents in the dissemination of blood-inhabiting protozoa than *M. domestica*. Patton recognized that the wounds produced by biting flies might be infected subsequently through the agency of non-biting blood-drinking muscids. His observations related to an Indian species named by Austen (1910) *M. pattoni*. Patton and Cragg also give a chapter on the haematophagous flies in their classical textbook, and emphasize their character and habits.

The Non-biting Muscid in Nyasa

In Nyasaland various species of these muscids abound, one in particular—*Musca spectanda* Wied—being, as recent work by W. A. Lamborn has shown, almost entirely dependent throughout its whole life on man. The eggs are laid solely on human excreta, on which the larvae feed to maturity. The adult flies, often in large numbers, especially in the early morning, settle on man, awaiting the opportunity to slake their thirst and deposit their eggs on his freshly excreted faeces. Swarms of non-biting haematophagous flies, including *M. spectanda*, may be found infesting abrasions and sores on domestic animals. They drink greedily the blood which oozes from the bites of *Tabanus*, *Stomoxys*, and other biting flies, and actually hustle them off in order to secure a meal. *M. spectanda* appears to be almost unique in the way in which it concentrates on man. It attacks persistently and with great determination scratches, wounds, open sores, tropical ulcers, yaw nodules, etc., and greedily drinks to repletion blood, serum, or secretions from the nose, eyes, or mouth. In one instance thirty-five *M. spectanda*, all females, were captured in three-quarters of an hour from a linear scab half an inch long on the dorsum of the foot of a native, when, despite the abundance of *M. domestica* in the neighbourhood, not a single specimen was included in the catch. Catches of fifty to sixty *M. spectanda* can be made readily within an hour in the early morning from the shoulders of any native.

These observations by Lamborn, and the hypothesis put forward by him (1932) concerning the part muscids may play in the spread, not only of trypanosomiasis, but also of cutaneous leishmaniasis, led to the experimental work described below, for which the senior author was largely responsible. As will be noted, the most important fact that has emerged is that this group of flies is capable of taking up and actively depositing blood-inhabiting protozoa and spiröchaetes, either by regurgitating them from the proboscis or by passing them unchanged and alive in the excreta over a period of five to six hours.

Mechanical Transmission of *Trypanosoma brucei* through the Agency of *Musca spectanda*

In these experiments over 200 flies, both bred and wild, were used. The usual procedure was to feed them on blood exuding from a puncture of the ear of a dog or from the tail of a rat infected with *T. brucei*. A certain proportion of flies thus fed commenced in about five minutes to pass in their dejecta either pure blood or blood-stained fluid full of actively motile trypanosomes,

while some flies continued to pass, at intervals, living trypanosomes for a period of at least six hours after an infective feed. A smaller proportion of flies were seen to blow a blob of blood containing living trypanosomes from their proboscis five or ten minutes after a feed.

Blood-stained excreta and regurgitation of blood were observed not only in the case of the flies fed on infected blood but in those fed on the normal blood of man and domestic animals and on other fluid material. The blood-passing capacity of various batches varied to a very marked degree. This variation may be associated, possibly with the food requirements necessary for the maturation of the ova in the female.

Thus in one experiment twelve flies were fed on a dog infected with *T. brucei*, and although numerous drops of clear excreta were passed over a period of five hours in no instance was either blood or trypanosomes detected. This batch of flies was killed after five hours, and motile trypanosomes were seen in the gut of eight of them.

In another experiment seven out of twelve of the flies fed on a dog infected with *T. brucei* commenced to pass drops of blood-stained excreta in from five to ten minutes, and continued to excrete numerous drops for five hours. All these drops contained active trypanosomes. One fly also regurgitated a drop of blood from its proboscis full of active trypanosomes.

Over a period of five hours one fly passed forty-one drops of dejecta, another seventeen drops, and a third fifty-three drops, all of which were blood-stained and contained living trypanosomes. As an example of the extraordinary capacity of this muscid to deposit living trypanosomes in its excreta it may be stated that a batch of ten, fed to repletion on the blood of a dog infected with *T. brucei*, passed in six hours 265 droplets stained with blood and containing living trypanosomes.

In carrying out experimental infections flies, after a feed on *T. brucei*, were placed in specimen tubes covered with gauze, and the drops of excreta containing living trypanosomes passed on to the sides of the tube were drawn up into a capillary in saline or citrate solution.

Into one rat excreta containing trypanosomes was introduced intraperitoneally, infection duly taking place. A second rat was successfully infected by placing a drop of excreta on a small fresh cut on the ear, and a third rat developed an infection with *T. brucei* after a drop of the fly's excreta had been placed on a drop of blood exuding from a fresh puncture made by a tabanid, *T. fraternus* Ric.

From the experimental observations here recorded there cannot be any doubt that, apart from any mechanical transmission by the action of biting flies *per se*, the combined action of these and the non-biting blood-drinking species is capable of bringing about the transmission of trypanosomes under natural conditions. The presence of hordes of these flies, which persistently infest and annoy both man and other animals—especially when abrasions or sores are present—is a significant fact when it is realized that their capacity for distributing viable trypanosomes is so perfect. Their predilection for the mucous surfaces, moreover, suggests a means whereby infection with trypanosomes may take place. Experimental work to test the possibility of infecting rats through the eye, nose, and mouth by the excreta of these flies containing *T. brucei* was, however, unsuccessful.

Passage of Living Leptomonads of the Cultural Forms of *Leishmania donovani*, *L. infantum*, and *L. tropica* through the Intestine of *Musca spectanda*

Observations on visceral leishmaniasis indicate that this form of the disease has the same geographical distribution as sandflies of the major group—*Phlebotomus argentipes* in India, *P. chinensis* in China, *P. perniciosus* in Italy,

Malta, and Algeria, and *P. major* in Greece. Cutaneous leishmaniasis, on the other hand, occurs where *P. papatasi*, *P. sergenti*, or *P. caucasicus* are found.

The problem of the relationship of these flies to the transmission of leishmaniasis has been ably reviewed by Wenyon, and more recently by Adler, and it would appear that the entire mechanism of transmission through their agency requires further elucidation. It is a curious fact that out of numerous attempts to transmit leishmania through the bites of infected sandflies very few positive results have been obtained. Shortt, Swaminath, and Krishnan recorded one successful transmission of *L. donovani* to a Chinese hamster through the bites of sandflies, and more recently Napier, Smith, and Krishnan report further successes. The numerous negative results in transmission through the bites of these flies is not easily explained when it is considered that the Chinese hamster is a very susceptible animal. Napier, Smith, and Krishnan (1933) have shown that both the rounded tissue forms and the flagellate forms of *L. donovani* can produce infection in hamsters when introduced intraperitoneally, subcutaneously, percutaneously, orally, and conjunctivally. A very high proportion of infections was produced by both forms of the parasite by all the routes tested, and it was further shown that except by the conjunctival route the flagellate form was always the more infective.

It would seem that, apart from infection through the agency of sandflies, direct or mechanical transmission by non-biting haematophagous flies of both visceral and cutaneous leishmaniasis is possible. Considering the capacity of these flies for taking up blood or tissue parasites, it is difficult to conceive of a more ideal method whereby all species of leishmania can be distributed to abrasions or to the conjunctiva, mouth, or nose, especially as this group of muscids is so well represented in the countries where leishmaniasis is endemic. Oriental sores during ulceration can be a source of infection to the flies, and in kala-azar of man and the dog involvement of the cutaneous tissues allows haematophagous flies easy access to the leishmania bodies. Moreover, as it has been shown that viable leishmania occur in the faeces of man, it is quite possible that the flies could ingest them and pass them on as a result of the habits already described.

Experimental Observations.—In our opinion the following experiments point definitely to the fact that all the species of leishmania in man could be transmitted directly to healthy individuals by these flies, either through skin abrasions, or through the mouth or conjunctiva.

Cultures of *L. donovani* (three different strains) of Indian origin and cultures of *L. tropica* and *L. infantum* (dog strain) were obtained from the London School of Hygiene and Tropical Medicine and maintained in Nyasaland. About 250 *M. spectanda* were fed in groups on these cultures, almost invariably to repletion, and, as in the experiments with *T. brucei*, many of the flies passed living leptomonads of all three species in their excreta from five minutes up to a period of three hours afterwards. One insect, fed on a culture of *L. donovani*, passed, during a period of three hours, twenty-three droplets of excreta containing living flagellates, and during the first five minutes after feeding regurgitated from its proboscis a drop containing them alive. A second fly, fed on the culture of *L. tropica*, passed in the same time thirty-one drops, all containing active flagellates, and a third, fed on a culture of *L. infantum*, passed eleven drops containing living leptomonads, also within the same time.

Unfortunately, owing to the fact that it was impossible to obtain the rounded tissue forms of the various species of leishmania, experimental work to ascertain the viability of these in the fly was not carried out, but from the work on the viability of trypanosomes and the flagellate forms of leishmania, it would seem to be practically

certain that these tissue forms would be readily passed viable in the dejecta of the flies over a period of several hours. It is hoped that an early opportunity may be made available to test this important point, as it is possible that during their sojourn in the gut of the fly some, at least, of the tissue forms may make an attempt to flagellate, especially if retained for several hours.

Passage of Living *Treponema pertenue* through the Gut of *M. spectanda*

In these experiments three cases of yaws were used, and about eighty flies, all of which were bred.

Before feeding the flies on the yaws sore, the presence of the causative organism was determined by dark-ground illumination and by staining. Two of the cases had spirochaetes numerous enough for easy detection after passage through the flies. The sores were then cleaned thoroughly to get rid of any surface pus, and the flies were allowed to feed on the exuding fluid. They did so greedily, and again a certain percentage commenced to pass fluid, which was found to contain living *T. pertenue*. In this experimental work the spirochaetes were only detected up to a period of one hour after a feed. Lack of time prevented a fuller determination of the period they will remain viable in the excreta of the flies.

Flies could infect any breach of the surface of the skin either through their dejecta or by regurgitation, as already indicated in the previous paragraphs. In this connexion it is significant that primary yaw sores have been recorded as arising not infrequently on such sites.

Summary

1. Non-biting haematophagous muscids feed readily to repletion on blood, serum, serous exudate, ulcers, sores, and also secretions from the nose, eyes, and mouth. After a meal a certain proportion of these flies pass blood or serum in their numerous dejecta, which may contain large numbers of living trypanosomes, leishmania, or the *Treponema pertenue* of yaws.

2. These haematophagous flies have their preferred hosts—for example, *Musca spectanda* Wied, which occurs in great abundance in Nyasaland, favours man. It lays its eggs exclusively in human faeces, breeding very freely; it derives moisture from human faeces, and could thus take up *L. donovani* from this source, since the organism is known to occur sometimes in this medium. Large numbers attack persistently and with determination scratches, cuts, and sores of the skin of man in search of food, and also haunt the eyes, nose, and mouth in search of fluid.

3. *Trypanosoma brucei* in the blood of rats and dogs are readily ingested by *M. spectanda*, and during a period varying between five minutes and six hours these flagellates can be passed alive in the numerous droplets of dejecta passed through the gut of the fly. Rats were experimentally infected by the intraperitoneal injection of these dejecta by placing a drop on a fresh cut on the ear and by placing the dejecta on a drop of blood exuding from the bite of a tabanid. *T. brucei* in the dejecta introduced into the eye, nose, and mouth did not produce infection. Certain flies after a feed extrude a drop of the ingested blood containing living trypanosomes from their proboscis five to ten minutes after a full meal.

4. Living leptomonads in cultures of *L. donovani*, *L. infantum* (dog strain), and *L. tropica* are freely ingested by *M. spectanda*, and are passed viable in the droplets of excreta for several hours after a feed. There can be no doubt that these flies could ingest the round tissue forms of all the human forms of leishmaniasis and pass them in a viable state either through the gut or by regurgitation from the proboscis to sores or mucous membranes. It would seem certain that both kala-azar and oriental sore could be actively transmitted through the agency of these flies.

5. *Treponema pertenue* of yaws passes rapidly in a viable form through the gut of *M. spectanda*, and so could easily be deposited on cuts and abrasions.

THE POST-OPERATIVE COMPLICATIONS AND RESULTS OF TONSIL AND ADENOID OPERATIONS IN CHILDREN*

BY

B. ELIZABETH NESBITT, B.Sc., M.B., F.R.C.S. Ed.

SURGEON, EAR, NOSE, AND THROAT DEPARTMENT, EDINBURGH HOSPITAL
 FOR WOMEN AND CHILDREN; FORMERLY CLINICAL ASSISTANT,
 EAR, NOSE, AND THROAT DEPARTMENT, ROYAL
 INFIRMARY, EDINBURGH

This clinical investigation into the post-operative complications and results of tonsil and adenoid operations on children under 14 years of age was suggested by Dr. J. S. Fraser, surgeon, ear, nose, and throat department of the Royal Infirmary, Edinburgh.

Source of Material

1. *Hospital Patients* (1,457 cases).—These cases were operated on as out-patients in the three years 1927–9 inclusive in Dr. J. S. Fraser's department. Out of the 1,457 hospital out-patients 1,138 reported at the Royal Infirmary, and 315 were visited at their homes by the hospital social service. The post-operative complications were considered in all the cases, but only in 1,138 of them were the operation results noted.

2. *Private Practice* (900 cases).—These patients were operated on in private by Dr. J. S. Fraser and Dr. W. T. Gardiner during the ten-year period 1919–28.

The following points were ascertained from the parents of each out-patient who reported, and by means of a questionnaire sent to each private patient's doctor: (a) occurrence of any post-operative complications; (b) disappearance of the preoperative symptoms; and (c) condition of the general health since operation.

The following routine is adopted in Dr. J. S. Fraser's department as regards the out-patient operations on children under 14 years of age. Only those who live within a radius of three miles from the Infirmary are operated on as out-patients. Exceptions are admitted as in-patients—namely, (a) very delicate children, or children with some complication requiring observation (for example, acute suppurative otitis media), and (b) patients living in overcrowded or unsuitable houses. The parent is given full written instructions as to the pre-operative preparation and post-operative care of the patient. The clinical assistants give the anaesthetics and do the operations (tonsil guillotine enucleation and removal of adenoids by curettes) under the supervision of the clinical tutor. When the haemorrhage has ceased the patients are put to bed in a ward for three or four hours after the operation. A clinical assistant examines each patient's throat before the parents take the child home in a taxi.

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Statistics

Preoperative examination of 1,138 hospital cases gave the following results:

Enlarged tonsils and adenoids	...	1,109 cases
Enlarged tonsils, no adenoids	...	10 "
Adenoids only (tonsils previously removed)	...	19 "
		1,138

There was a previous history of a peritonsillar abscess in three cases, and a fourth patient presented himself for operation, but owing to the existence of a peritonsillar abscess his tonsil was not removed.

Operations in the 1,138 hospital and in the 900 private cases were as follows:

	Hospital	Private
Tonsils and adenoids removed	1,089	825
Tonsils only	10	0
Adenoids only	39	75
	1,138	900

Results of tonsil and adenoid operations in the private and hospital cases:

	Hospital per cent.	Private per cent.
Tonsils		
Complete enucleation	80.3	97.0
Incomplete enucleation	19.0	3.0
Results unascertained (refused examination)	0.7	—

Complete enucleation of one tonsil with the guillotine and dissection of the other was done in eleven of the private cases.

	Hospital per cent.	Private per cent.
Adenoids		
Complete removal	81.8	99.5
Adenoids remains	17.5	0.5
Results unascertained (refused examination)	0.7	—

The above percentages of incomplete tonsil and adenoid operations are somewhat high in the hospital cases, but these operations were done and the anaesthetics given by thirty-three successive clinical assistants.

Post-operative Complications

The material reviewed below comprises 1,457 hospital and 900 private patients.

HAEMORRHAGE

In all cases, to safeguard against avoidable haemorrhage, a careful inquiry was made as to any tendency to haemorrhage—for example, from an ordinary wound or tooth extraction. If the patient was known to be a haemophilic the coagulation index of the blood was ascertained and appropriate preoperative treatment adopted. In the groups of hospital and private patients under consideration there was no case of congenital haemophilia.

* Attention to some points in the preoperative preparation and immediate post-operative treatment of the patients is productive of quick haemostasis. They are: (1) preliminary injection of atropine sulphate, (2) short ethyl chloride anaesthesia, (3) the use of a blunt tonsil guillotine and sharp adenoid curette, and (4) immediate post-operative treatment: this consists of sponging the face and neck with ice-cold water, and the adoption of the sitting position when the patient has recovered from the anaesthetic.

It should be noted that the age of the children is important, as under 14 years severe haemorrhage occurs less frequently than in older children.

Reactionary Haemorrhage.—Out of 1,457 hospital cases sixteen (slightly over 1 per cent.) had some reactionary

haemorrhage; this was slight in fifteen patients, but severe in one. In all cases the haemorrhage stopped spontaneously. Out of 900 private patients reactionary haemorrhage occurred in ten cases (1.1 per cent.). This was slight in eight (one from adenoids only) and severe in two, requiring special treatment to arrest it.

Secondary Haemorrhage.—In the hospital series fourteen cases (1 per cent.) of secondary haemorrhage were reported. This was slight in eleven cases and severe in three. Two of the latter were admitted to the Royal Infirmary, and one of them required special treatment to arrest the haemorrhage. The onset of the haemorrhage occurred on or between the second and seventh days after the operation. This is important, as hospital in-patient tonsil and adenoid cases are usually detained in hospital for only forty-eight hours. In the private series secondary haemorrhage was slight in one case (0.1 per cent.).

Thus we see that while in the private patients two cases of severe reactionary haemorrhage occurred, in the hospital there were three cases of severe secondary haemorrhage. No case of collapse or shock occurred from haemorrhage. The tendency to bleed shown in the above thirty hospital cases could not be credited entirely to partial removal of tonsils and adenoids, for later examination showed that in eighteen cases the operation was complete, while in only five cases were the tonsils incompletely enucleated and in seven there was still some adenoid tissue present.

AURAL SYMPTOMS AND COMPLICATIONS

Earache.—Fifty hospital patients (3.4 per cent.) and twenty-five private patients (2.8 per cent.) complained of post-operative bilateral earache. The earache was probably a reflex otalgia from the operation area, via the glosso-pharyngeal nerve. Analysis of the preoperative histories of these cases showed that six of the private patients had preoperative pathological aural conditions predisposing them to attacks of earache—for example, one had scars in the tympanic membranes, four had previously had acute suppurative otitis media, and one had had a left Schwartz operation. In addition, two had previously suffered from earache.

Acute suppurative otitis media occurred shortly after operation in one private patient (0.1 per cent.), as compared with twenty-two hospital patients (1.5 per cent.); in half of them it was unilateral, in half bilateral. In the preoperative histories of these twenty-two patients the following factors had predisposed to an acute otitis media. Ten cases had complained of frequent colds, two of earache, and twelve of deafness. Of the latter, four had catarrhal otitis media and one had scars in the tympanic membranes. In the post-operative examinations another factor was revealed as influencing the incidence of otitis media after operation—namely, the incomplete character of the operation. In six cases the tonsils were enucleated incompletely, and in nine cases remains of adenoids were still present. The end-result in fifteen of the nineteen cases examined was cessation of the otorrhoea within fourteen to twenty-two days. Three cases went on to chronic suppurative otitis media, and one case had recurring attacks of acute suppurative otitis media. On examination, it was found that the perforations in the tympanic membranes had healed in fifteen cases, and persisted in four cases in the following positions: two central, one anterior, and one posterior.

SEPTIC THROAT

In the hospital patients there were four cases (0.22 per cent.) of septic inflammation of the throat with pyrexia and local inflammatory changes on the tonsillar fossae. No similar condition occurred in the private patients.

NASAL CATARRH

There were twenty-six hospital cases (1.8 per cent.) in which nasal catarrh supervened on the operation. In twenty-five of these it lasted only four days, but in the remaining case it developed into a chronic nasal catarrh lasting for a few months; five months after operation there was no macroscopic pathology in the nose, and an x-ray film of the nasal accessory sinuses showed no comparative obscurity; the patient had recovered. There was post-operative nasal catarrh in only two (0.2 per cent.) of the private patients. These children had previously complained of frequent colds, mouth-breathing, and deafness. In both cases the ultimate result of the operation was satisfactory, and all the preoperative symptoms were cured.

PARESIS OF SOFT PALATE

In the hospital series there were eight cases (0.5 per cent.) of paresis of the soft palate. All complained of difficulty in swallowing and of fluids regurgitating through the nose; six of them were very ill and feverish. All cleared up spontaneously within seven or eight days. The soft palate was injured in one private case (0.1 per cent.) at operation. Recovery was slow, but the symptoms gradually disappeared.

TORTICOLLIS

There were five hospital cases (0.35 per cent.) of torticollis. All recovered; four were well in three days, but one patient had a stiff neck for three weeks, which eventually cleared up with special treatment. No private patient suffered from this symptom.

CHEST SYMPTOMS AND COMPLICATIONS

Cough, lasting for a few days after operation, without pain, sputum, physical signs, or constitutional disturbance, occurred in twenty-six hospital patients (1.8 per cent.). No pulmonary complications occurred in the private cases. There were five cases of pulmonary disease among the hospital patients (0.35 per cent.). All recovered, the bronchopneumonia within six weeks, and the other cases within three weeks. The operation had been done completely in all. These cases are briefly summarized below.

Pneumonia: Case 1.—Female, aged 5 years, following operation on 12/1/28 developed a right upper lobar pneumonia: recovery complete. Case 2.—Female, aged 9 years, after operation on 9/11/29 developed pneumonia: recovery.

Bronchopneumonia: Case 3.—Bronchopneumonia occurred in a male aged 8 years; operation on 4/7/29: recovery.

Pleurisy: Cases 4 and 5.—Two cases of pleurisy (one aged 8 and the other 10 years) occurred following operation on 25/6/27 and 29/8/29 respectively: recovery.

SEPTIC RASH

Septic rash occurred in one case (0.07 per cent.). Previous to operation this patient had a follicular tonsillitis, so that a good deal of infection was present. The septic rash appeared four days after the operation, and disappeared after a purgative was administered. No case of septic rash occurred in the private patients.

SEPTICAEMIA, TOXAEMIA, AND PYREXIA

There was one hospital case of septicaemia after operation. He made a good recovery within three weeks. No case of septicaemia occurred in the private patients.

Toxaemia, due to toxic absorption from the operation areas, occurred in two private cases (0.2 per cent.). Both patients were in a nursing home for four days, and had a rise in temperature for some days after returning home.

Pyrexia, due to persisting preoperative cervical adenitis, occurred in two private cases (0.2 per cent.). Operation

muters were operated on for enlarged tonsils and adenoids, but were, of course, not benefited as regards their hearing.) Attacks of earache recurred in forty-five out of 152 cases after operation. Tinnitus in two patients (aged 8 and 12 respectively) disappeared. Acute suppurative otitis media healed in twenty-nine out of thirty-one cases, and chronic suppurative otitis media healed in fifty-six out of eighty-nine cases.

Patients complaining of headache (fifteen) and nocturnal enuresis (two) were not improved.

General Summary of Results in 1,138 Hospital Patients

The local symptoms for which the operation was recommended were completely cured in 851 (75 per cent.), partly cured in 204 (18 per cent.), but persisted in eighty-two (7 per cent.).

There was a marked improvement in general health in 982 (86.4 per cent.), but no improvement in 139 (12.2 per cent.). There were seventeen cases (1.4 per cent.) examined three weeks after operation—that is, too soon to estimate improvement in general health.

Discussion and Summary

On reviewing the post-operative symptoms and complications one sees that their total percentage is higher in the hospital patients (13.02 per cent.) than in the private patients (5.3 per cent.). If we exclude symptoms—for example, earache and cough—and complications—such as, exanthemata—we find that the percentage of 7.54 for complications in the hospital patients still remains higher than in the private patients (2.2).

The difference between the two figures can be accounted for as follows: (a) Some inherent factor is probably present in the preoperative condition of the hospital patients. Their general nourishment and constitution are, as a rule, inferior to those of the private patients, while in this hospital series several patients had predisposing factors in the causation of aural complications, and a number of them were possibly operated on in the prodromal stages of the exanthemata. (b) The results of hospital operations carried out by junior operators are not so good as those done by experienced surgeons in private practice. (c) Complications may be due to chill on the journey home in a taxi after operation; this was a possibility in the five cases of pulmonary complications, though the aspiration of septic blood clot during the operation—for example, in the case of bronchopneumonia; or of septic embolism from the operation area, as in the atypical case of pneumonia (right upper lobe) and in the two cases of pleurisy—cannot be excluded. No lung complication occurred in the private cases. (d) The only case of death after discharge from the Royal Infirmary was the case of meningitis. (e) No complication was found due to neglect of the parents to carry out written instructions given them for the preoperative and post-operative care of the children.

In this series of hospital out-patients, for whom every precaution was taken as to the general state of their health, their preoperative preparation, conveyance from the Infirmary to their homes, and the suitability of their homes for convalescence, the total percentage of complications was rather more than twice as high as that in the private cases. Considering the nature of some of the complications recorded in hospitals—for example, temporary torticollis, paresis of the soft palate, and nasal catarrh—the difference in the percentages is hardly of sufficient importance to make us condemn the present out-patient operation system and recommend hospital authorities to provide beds for all tonsil and adenoid cases. One acknowledges that the ideal post-operative treatment for these cases would be to detain the patient

in hospital for at least forty-eight hours after the operation, but even with this precaution complications may occur. In support of this there are the statistics published by J. A. Keen in the *Journal of Laryngology* (January, 1932) in an article entitled "Medical and Surgical Complications of Tonsillectomy in Childhood." In his series of 9,344 cases each patient was kept in hospital for at least twenty-four hours after operation; sixty-six cases (0.66 per cent.) of aural complications occurred, consisting of sixty cases of acute suppurative otitis media and six cases of mastoiditis (including three deaths from this cause), as compared with our twenty-two cases (1.5 per cent.) of acute suppurative otitis media (no mastoiditis, and no deaths) in the Edinburgh hospital cases. Further, there were five cases of septicaemia (0.05 per cent.), including one death; in Mr. Keen's group, as compared with one case (recovery) (0.07 per cent.) in the Edinburgh group.

I wish to thank Dr. J. S. Fraser and Dr. W. T. Gardiner for allowing me to use the records of their private patients; also to acknowledge my indebtedness to Dr. J. S. Fraser and Dr. Logan Turner for their interest in, and helpful criticism of, this paper. Finally, I should like to thank Miss Watt and other members of the Royal Infirmary of Edinburgh Social Service Department for the records they obtained for me of cases which did not report for examination.

PULMONARY TUBERCULOSIS IN ASTHMA CASES

BY

ERNEST M. FRAENKEL,

WESTMINSTER HOSPITAL TUBERCULOSIS RESEARCH FUND

Among 522 cases of asthma seen in recent years there were 369 which I have investigated with a uniform method between 1930 and 1932—200 men and 169 women of the working class in active employment. In all of these cases a detailed examination was made both by clinical and x-ray methods for any signs of active or healed tuberculous lesions in the lungs (E. Fraenkel').

Evidence from the Literature

The view that asthma and pulmonary tuberculosis are mutually exclusive is widespread in this country as well as abroad. Regarded from the statistical point of view there is undoubted justification for this attitude. The work of Schroeder,² for example, shows that out of 4,716 cases of pulmonary tuberculosis only thirty cases showed typical symptoms of asthma. Kaemmerer,³ an experienced German clinician, considers that tuberculosis plays no part in the genesis of asthma. Bandelier and Roepke⁴ believe that asthma may produce some immunization against the disease. In support of this we have the observation that tuberculous guinea-pigs appear to be protected against horse-serum shock; this is explained by Pagel⁵ as due to diminution of antibody formation, which is dependent on the number of tuberculous foci. In conjunction with Pulvertaft⁶ I have recently been able to show that a similar protection may be obtained by massive and repeated injections of Calmette's B.C.G. On the other hand, a single dose or the injection of dead or damaged B.C.G. was ineffective, and did not produce a local lesion. These results would seem to support in some degree the hypothesis of Pagel.⁵

Such authors of standing as Liebermeister,⁷ Krez,⁸ Zdansky,⁹ and Wernscheid,¹⁰ however, insist that the majority of asthma cases are of tuberculous origin. Harkavy and Hebal,¹¹ working at the Mount Sinai Hospital, report in a series of 400 asthma cases over 10 per

cent. as being tuberculous. Among these 400 cases eighteen were examined very thoroughly by the x rays, and seventeen of these showed cavities. In 1912 I¹² observed a case of bronchial asthma in which a tuberculous bacillaemia could be demonstrated by animal injection. Two cases of Kenner¹³ and Loewenstein in 1931 gave similar results. Further evidence of a relationship between these conditions is presented by the demonstration of a filterable tuberculous virus in a case of asthma by Sergeant and Kourilsky.¹⁴ Jiminez Diaz¹⁵ is of opinion that tuberculous allergy may bring about asthma, and later there may ensue a hypersensitiveness to other substances. On the other hand, Tauxk¹⁶ is of opinion that asthma may predispose to tuberculosis. That tuberculosis is activated and accelerated by asthma is held by Lueg.¹⁷ Opposed to this is the statement by Schroeder¹⁸ that frequently in cases of coexisting asthma and tuberculosis the latter is of the slow and relatively unprogressive kind. The classical work of the late Professor von Pirquet¹⁹ has made us familiar with the allergic phenomena associated with tuberculous infections. We are thus always faced with the possibility that this sensitization may be extended to other allergens.

Apart altogether from the theoretical significance of the simultaneous appearance of the two conditions, there can be no doubt, as has been shown by my own investigations,¹ by Eichhoff,²⁰ and by Hamann²¹ working at my suggestion, that a careful investigation and assessment of a large number of asthma cases will reveal the presence of active, even cavernous, tuberculosis in some of them. Hamann has reported on eight of my cases with asthma and active tuberculosis, of which two died and two others developed tuberculosis within two years. The facts which I wish to present here are of a similar nature to those of these two authors, except that they rest upon a considerably larger material.

Results of Investigation

The 369 cases of my series were all sent to me with the diagnosis of bronchial asthma by medical men, among whom were specialists in pulmonary diseases. Investigation showed that, of these, sixteen patients had active tuberculosis. They could be classified as follows: four of open tuberculosis with demonstrable bacilli in the sputum, four others having cavities without demonstrable bacilli, and eight others with active tuberculosis both clinically

Pulmonary Tuberculosis in Cases of Bronchial Asthma

	Males (202)	Females (169)	Total (369)
Open tuberculosis	3 } 10* (5 %)	1 } 6 (3.5 %)	4 } 16 (4.3 %)
Active tuberculosis	7 }	5 }	12 }
Inactive tuberculosis	17 (8.5 %)	9 (5.3 %)	26 (7.0 %)
Healed tuberculosis	17 (8.5 %)	3 (1.75 %)	20 (5.4 %)
Total cases ...	44 (22 %)	18 (10.5 %)	62 (16.7 %)

* 4 had cavities.

and roentgenologically. Of the sixteen only one case had been sent with the diagnosis of asthma and tuberculosis. In addition to this we found in twenty-six other cases definite evidence roentgenologically of productive cirrhotic inactive tuberculosis. Finally, twenty further cases showed healed lesions. That is to say, that of the 369 asthma cases sixty-two (16.7 per cent.) showed signs of present or past tuberculous infection.

Discussion

The epidemiological importance of tuberculosis undiagnosed on account of the concurrent symptoms of

asthma is at once obvious. In two instances a suggestive history was obtained. In one the undiagnosed patient's wife developed tuberculosis of the eyes, and in another two children had tuberculous meningitis and pulmonary tuberculosis. Eichhoff²⁰ and Hamann²¹ have also drawn attention to this danger, and there can be little doubt that it merits our serious attention. It would appear also—and I shall give an example of this—that a tuberculosis may become established after asthma alone has been recognized. Of course, the asthma may, as a result of an allergic predisposition, be at first monovalent, later becoming polyvalent. The possibility of a secondary hypersensitiveness to tuberculous allergens now arises. Thus, a chemist's assistant who possessed a sensitization to sodium salicylate with typical asthma later developed under our observation a rapidly progressive exudative tuberculosis with persistence of the asthmatic picture. That this patient had previously been completely free from tuberculosis there could be no doubt. Another case was that of a medical man who had had asthma practically all his life and became infected with tuberculosis whilst working in the tuberculosis department of a hospital. This infection led to cavity formation, and after treatment at Davos was followed by healing. The investigation of this asthma case is still continuing. On the other hand, the history of the patient frequently shows an "influenza" infection or a catarrh of the apex. In some of such cases there is found an inactive tuberculosis, which can only be demonstrated by the x rays.

The most important aspect of these observations is the fact that an active and open tuberculosis can be concealed for a lengthy period under the guise of a bronchial asthma with both eosinophilia and skin reactions against specific proteins.

E. J. Canal Feijoo (*Rev. Med. Latino-Americana*, June, 1934), writing from the province of Santiago del Estero, draws attention to anomalous forms of leishmaniasis met with in his region and not described before. As they differ so widely from the ulcerative, impetiginous, ethymoid, nodular, verrucous, framboesic, and non-ulcerative varieties, of which many observers have written, he considers them as constituting a true morbid entity, even though they are caused by the same germ. In great detail, and illustrated by a wealth of excellent photographs, he describes these indigenous forms as trichophytoid, erythematous-pigmentous, oedematous, and mucous, and gives the history of the evolution of each. From his communication it may be concluded that kala-azar, like other diseases, assumes aspects which differ in various regions owing to the influence exerted upon the germ by different telluric, climatic, and meteorological conditions.

Clinical Memoranda

UNREDUCED OCCIPITO-POSTERIOR PRESENTATION WITH SHORT CORD

The following account of a recent personal case seems of sufficient interest to be recorded.

The patient, aged 23, and formerly a typist, started labour at 6.30 p.m. two days after the estimated date. Abdominal palpation suggested an occipito-posterior position. At 4 a.m. on the following day dilatation was complete, the membranes ruptured, and the child's head descended lower in the occipito-posterior position. At 5.10 a.m. the presenting portion of the head was visible at the vulva. The pains were good, but not frequent, and the head could be observed rotating into the occipito-anterior position. When rotation was complete, the head was born at 7 a.m. With a sudden movement—almost amounting to a jerk—the head at once returned to its former occipito-posterior position, and there was no further progress in the birth. Considerable traction was necessary before the shoulders were born, and the anterior arm had to be completely extracted first. There being again no further progress, the head was pushed on to the mother's abdomen and steady traction was required to secure birth of the legs. An abnormally short umbilical cord was then discovered, which had prevented rotation of the child's body. This had to be divided with the child's abdomen pressed closely against the mother's vulva. Apart from the need for three perineal stitches and the subsequent occurrence of a slight prominence of the child's umbilicus, there were no ill effects from the tension on the cord. The third stage was normal, being accompanied by considerably less bleeding than is usual. The weight of the child was 7½ lb. Unfortunately no actual measurement of the cord was made.

London, S.W.11. F. P. N. PARSONS, M.B., M.M.S.A.

BILATERAL RUPTURE OF THE TENDON OF EXTENSOR POLLICIS LONGUS

In the literature at my disposal I can find no reference to a case of bilateral rupture of this tendon from any cause. It seems, therefore, that a record of the case might be of interest.

On March 5th, 1932, a motor mechanic, aged 30, was brought to my house following an accident with his motorcycle, in which he was thrown into a ditch. He landed with his right hand doubled under him and the left hand extended in front. On examination the only wounds found were several superficial cuts about the hands. On the right hand there was a fair-sized cut extending from the first interphalangeal joint of the thumb to the back of the wrist, midway between the tubercle of the ulna and Lister's tubercle. It was not deep, and did not display the superficial fascia. On the left hand, over the "anatomical snuff-box," was a large bruise. The remaining abrasions were only superficial. No bony injury could be detected in the damaged regions, either by clinical examination or by radiography at a later date. The movements of both thumbs, although painful, were of normal range. The man received the usual treatment with antitetanic serum, and after cleansing the wounds they were dressed with tincture of iodine.

On March 9th the patient returned to tell me that he had felt something "go snap" in his right thumb while at work that morning. Since this he had not been able to use his thumb because of difficulty in manipulating the end. In fact, it was easy to confirm the man's statement, as he held his thumb up to view when he entered my room. The terminal phalanx drooped and could not be extended. Other movements were unaffected. The wound was dry, and healing in the normal manner; the swelling from bruising was almost gone. The tendon of the long extensor of the thumb could not be made out as a boundary of the "anatomical snuff-box."

It was decided to explore the region of the wound where it crossed the long extensor tendon. Accordingly, on March 10th, the wound over the thumb and the wrist was excised; the anaesthetic used was a "nerve block" at the elbow with

2 per cent. novocain, 15 c.cm. in all being used. This gave a perfect anaesthesia of the area of operation. The tendon was easily displayed, and there was found to be a rupture about half-way across its course as the boundary of the "snuff-box." The proximal end of the tendon was not in view. The ruptured end of the distal part was not ragged, but had the appearance of being cut with a not too sharp knife. The surface appeared normal and shiny. The small branch of the radial nerve proceeding up the radial side of the index finger crossed the tendon exactly at the point of rupture, and showed the effects of this relation in the form of a tiny blue fusiform swelling. (No area of anaesthesia had been detected previously.)

Search was now made for the end of the proximal part of the tendon, but was fruitless. The exploration was carried as far as the posterior annular ligament without result. An Esmarch bandage was applied from above down, but proved equally ineffective in bringing the end of the tendon into view.

With the state of affairs thus, it was decided to split the tendon of the extensor of the index finger, and having passed the distal end of the ruptured tendon through the split and back again, to suture it in this position. This was easily done, and the wound duly closed without drainage. The hand was then well wetted with surgical spirit, dried, and the dressing applied. A palmar plaster cast was then made to maintain the thumb and index in extension.

On March 21st the whole of the splintage and dressing was removed and the sutures taken out. The wound had healed neatly and firmly. The splint was cleaned, repaired, and

The smaller illustration shows the method of fixing transplant.

reapplied. The hand was inspected several times during the next eighteen days, passive movement being applied during this time. Active movements were started on April 12th. These were free but somewhat clumsy. The scar was healthy and firm without being adherent to any underlying structures.

In the meantime, on March 19th, the patient suffered an exactly similar occurrence to the left thumb: on this occasion the gap in the tendon could be felt in almost exactly the same place as the rupture had occurred on the right. Suffice it to say that on exploring the tendon the two ends were found little separated, being held together by some slight fibrous reaction, no doubt due to the resolution of the large haematoma that had occupied this space at the time of the accident. The ends of the tendon at the rupture were not sharply "cut" as they had appeared on the right side, but frayed and unhealthy-looking; there was a strong resemblance to a piece of string which had been cut through by fraying it on the edge of a sharp stone. The tendon sheath was adherent, both above and below the site of rupture.

The ends were cleaned and sutured with fine catgut. The obstructing fibrous tissue was cleared away as far as possible, and the wound closed, no attempt having been made to clear the adherent tendon sheath. The same procedure was carried out with this thumb as has already been described for the right thumb. The wound healed by first intention, and active movements were obtained after twelve days from the time of operation.

Now (March, 1933) I have seen the patient again in order to see the result. The left thumb functions as it normally did before the accident. The right thumb has improved remarkably, and functions nearly as well as before, but is a little awkward at times, when fine movements are required. The patient finds nothing to complain of in either hand, and can do all his work without any trouble.

Reviews

GREEN'S PATHOLOGY

In editing the fifteenth edition of *Green's Manual of Pathology*,¹ Dr. H. W. C. VINES has not only submitted the book to a drastic revision, but has greatly enlarged it. The present volume is more than one-third larger than its predecessor, the 650 pages of the latter having been increased to 930. Moreover, 150 new illustrations have been introduced, and over a hundred of the old figures replaced by new ones, all of them of the best quality. In carrying out the revision Dr. Vines has had the assistance of Dr. K. M. Lynch, professor of pathology, South Carolina. The original division of the work into general and special sections has been retained, the author noting with disapproval the tendency to combine the two which is exhibited in some of the recent textbooks. In other respects the order adopted in the last edition has been considerably altered, as shown in the table of contents, which has been amplified in details and thus rendered more useful.

Additional chapters have been written on avitaminosis, diseases of the ductless glands, diseases of the breast, and diseases of the genital tract. Many sections and chapters have been amplified and brought up to date, the section on tumours of the brain, for example, having been nearly doubled; on the other hand, in a few instances the descriptions have been rendered more concise, as in the general account of tumours, which has been reduced by twenty pages. All sections show evidence of careful revision and of an endeavour to introduce such modern views as experience has proved to be sound, as in the description of the cells involved in inflammatory processes. It may be said that the editor has produced what almost amounts to a new book, yet it still retains the characters of the original *Green's Pathology*, which has probably always been the most popular textbook on the subject among English students, and in its new edition deserves to remain a favourite.

HEATING AND VENTILATION

The heat losses from the body of man are effected by means of radiation, convection, and the evaporation of moisture. When one of these processes is checked another develops compensatory activity, but they are not all equally comfortable, and their due adjustment so as to reduce discomfort, where the environment is amenable to control, is always important. Problems thus present themselves in the heating and ventilation of buildings for which engineers have devised solutions. Engrossed, however, in the mechanical or other complexities of practical schemes, the technical textbooks have been apt to pass too lightly over the fundamentals. To fill this gap Dr. H. M. VERNON has written a book² on the principles which underlie, or should underlie, current practice in these matters.

After referring to the kata-thermometer scale and the Pittsburg effective temperature, the author describes the eupatheoscope and the globe thermometer, which take account of radiation. He indicates how loss of heat by buildings may be reduced. He says of the coal fire that with its flue on an inner wall as much as 50 per cent. of the total heat goes to warming the house. The various methods of heating by hot water and steam are considered. The long low wall-type hot-water radiator

beneath the whole length of windows receives commendation. The account of low-temperature radiant heating includes the panel system with embedded hot-water pipes, the non-embedded panels or rayrads, under-floor heating by air ducts as in Liverpool Cathedral, electric panels, and also electric tubular heaters.

In the chapter on natural ventilation the laws of flow in air circuits are cited, and the importance urged of having a ventilating flue in every habitable room. While natural ventilation through chimneys and flues is usually adequate for private houses, it may not suffice for schools, assembly rooms, and factories. In the chapter on mechanical ventilation the upward and downward methods for places of assembly, where lateral distribution might be difficult, are compared with one another. On the upward plan the fresh air is introduced low—in the House of Commons at floor level, in the Cambridge Examination Hall seven feet above the floor—and exhausted at the ceiling. On the downward plan—exemplified in the United States Hall of Congress and the Empire Cinema, London—the fresh air enters by way of the ceiling and is withdrawn at floor level. The concluding chapters deal with the control of humidity and air conditioning in industry.

The foregoing summary may convey some impression of the scope and contents of Dr. Vernon's book. Its merit can be fully appreciated only by perusal and study. We cordially recommend it, for guidance and information, not only to engineers, but to medical officers, factory inspectors, sanitary officials, and others who are concerned in their several ways with heating and ventilation.

NEPHRITIS.

Dr. ROBERT PLATT'S *Nephritis and Allied Diseases*³ is an excellent account of present-day knowledge. It is no mere compilation; the author has studied the authorities, but has in addition expressed his own views in writing the various divisions of the subject. That these views are orthodox and at the same time up to date makes the book a valuable one to place in the hands of the senior students and practitioners for whom it is designed. After a short introduction on the structure and function of the kidney, Dr. Platt discusses the renal function in disease, following mainly the modern theory of kidney secretion propounded by Cushny and elaborated by Verney and his co-workers, and the methods by which renal functional capacity is assessed. These are adequately and clearly dealt with. The clinical section which follows constitutes the main part of the book. Here the reader will find a full description of the aspects of the form of nephritis, chiefly seen in young people, in which three stages can frequently be recognized: an acute onset with haematuria and oedema, a prolonged oedematous stage, and a terminal stage without oedema. The two latter stages may be separately named "subacute" and "latent" respectively, and are followed by a chronic stage in which renal insufficiency has developed.

Many names have been proposed by the various writers on Bright's disease for these stages and the varied combinations of them which are met with in patients. Practitioners will find that Dr. Platt's descriptions will enable them to place their own cases under the appropriate heading so that the indications for treatment which he has so well detailed may be applied. The kidney changes and alterations of renal function in pregnancy, in hypertension and generalized vascular disease, in bacterial infections of the kidney and in affections of the renal pelvis and urinary tract are described, together with the treatment to be adopted. The reader will find a series of diet lists which can be used in hospital or private work, in-

³ *Nephritis and Allied Diseases: Their Pathology and Treatment*. By Robert Platt, M.D., M.R.C.P. London: H. Milford, Oxford University Press. 1934. (Pp. 166. 7s. 6d. net.)

cluding two examples of ketogenic menus for the induction of acidosis in the treatment of coliform affections of the urinary tract. At the end of each section there are a few clinical histories illustrating the actual course of typical cases of the condition described. Dr. Platt's book strikes one as having just that amount of theory which makes the subject interesting, and the practical part is wholly good.

OBSTETRICS AND GYNAECOLOGY

The sixth volume of the *Practitioners' Library of Medicine and Surgery*, dealing with *Obstetrics and Gynaecology*, is a handsome and clearly printed book, which runs to about 1,000 pages, a generous amount of space being devoted to lists of contributors, tables of contents, and index. The general purpose of this library is to "present material which is pre-eminently of practical utility to the man in general practice." Most of the contributors are apparently relatively junior men of the status of associate professor or instructor. The article on diseases of the uterus is by a clinical associate in surgery of the University of Oregon.

The opening chapter deals appropriately enough with development. In order to obtain an insight into the difficult subject of embryology the reader is advised that "the mind must conceive of four functions simultaneously—length, breadth, depth, and time." The practitioner need not be discouraged at being asked to visualize these abstractions as functions, for the descriptions which follow are clearly written and well illustrated. A short section on the chronology of foetal development is particularly interesting and useful. In discussing the hygiene of pregnancy the author, Dr. Emerson L. Stone of New Haven, strikes a note of optimism which is hardly justified when he writes that pre-natal care and the development of obstetrics have been "the chief factors in the achievement of a negligible rate of morbidity and mortality for mother and child." The view that the present rate of maternal mortality is negligible is certainly not shared by the senior obstetric teachers in the United States, as has been shown by recent reports from the White House Conference and the New York Academy of Medicine. The detailed advice given about ante-natal care and about the home equipment necessary for a confinement is sound and adequate.

Professor Karl L. Wilson of Rochester, N.Y., has contributed an admirably written and well-illustrated account of normal labour, which readers of this System will value as a reliable and practical guide. In discussing the physiology of the puerperium full consideration is given to recent experimental work on the hormonal influences which excite and regulate lactation, while the possible influence of the placenta as an inhibitor of lactation is also considered. In this article an admirable balance is maintained between scientific advance and practical requirements, for the clinical details dealing with the process of nursing and the care of the breasts are entirely praiseworthy. Many useful recommendations with regard to posture and exercises are also given. One of the most interesting contributions is that of Professor Thoms of New Haven on the pathology of labour and the puerperium. In writing of subnormal expulsive forces the wise remark is made that women who show "more or less marked asthenic tendencies cannot be expected to be athletes in the process of parturition." The treatment recommended for inertia in the first stage is one-quarter to one-sixth of a grain of morphine, and, after the patient has slept, one to two ounces of castor oil, followed by the controlled use of pituitrin by intranasal application until labour is actively progressing. Dealing

with the prevention of post-partum haemorrhage, Professor Thoms states that it is his rule never to leave the bedside of a patient for at least an hour, even if a competent nurse is in attendance; this is an admirable example for a teacher to set his students.

The description of gynaecological conditions has been considerably abbreviated by the omission of all details of operative procedures. The clinical pictures are, however, well drawn both with pen and with pencil, and the aim of the contributors in this part of the work has clearly been to emphasize only those aspects in which the general practitioner is directly interested. It cannot be doubted that the American doctors who consult this work and follow its advice will be well equipped in the departments of obstetrics and gynaecology.

LATENT PLUMBISM?

The reader will be somewhat surprised to discover that under the title of *The Menace and Geography of Eclampsia in England and Wales* Dr. NORMAN PORRITT has developed the disturbing hypothesis that a considerable section of the population of this country is either actually suffering from, or is exposed to the menace of, a latent form of lead poisoning. The author's thesis is that a mild form of plumbism exists, hitherto unrecognized by the medical profession, which reveals itself, not by the classical signs and symptoms, but by a symptom-complex which in fact (although the author does not say so) resembles that of general neurasthenia. The proof of this hypothesis offered to the reader is that a series of such cases have come under the personal observation of Dr. Porritt, in which the subjects were found to be drinking water which contained a variable amount of lead, and were also excreting lead in the urine. Some of these persons who went away from home for a change were relieved thereby of their symptoms, but the reader is not told that the drinking water in the new places of abode was shown by analysis to be free from lead. In no case apparently was it demonstrated that along with the disappearance of the symptoms the urine became free from lead, nor is it shown that the severity of the symptom-complex was proportionate to the amount of lead in the water or to the amount excreted in the urine. The author's lament that he failed to convince the medical officer of health of the town in which he then practised of the truth of his theories seems scarcely justified. Who could be convinced by such incomplete evidence?

In this book Dr. Porritt advances the further theory that lead in drinking water, even in very small amounts, constitutes a predisposing cause of abortion and of eclampsia. The evidence adduced is that the mortality from "eclampsia and other accidents and diseases of pregnancy" is higher in districts supplied with soft, plumbo-solvent water than elsewhere. Dr. Porritt rightly draws attention to the well-known abortifacient action of lead exerted through its destructive influence upon chorionic tissues. Lead also injuriously affects the functional activity of the kidney, and so may predispose to the occurrence of eclampsia. All this is undoubtedly possible, but unfortunately the statistical material requisite for properly testing the theory was not available to the author. The group figures upon which he relies include other causes of maternal death of equal importance to eclampsia. It would seem very improbable that the Public Health Service can have overlooked a latent form of plumbism due to potable water, as the author would have us believe. In any case the questions he raises are for the medical officer of health, not the obstetrician, to deal with.

OCULAR ASTIGMATISM

Astigmatism of the refractive media of the eye was first discovered by the English physiologist Young in 1801: twenty-six years later the Cambridge astronomer Airy made the first correction of the defect by the use of cylindrical lenses. Since then there have been many investigations into the causes of the defect. At one time, owing to the work of Javal, there was a tendency to ascribe the finding to irregularity of the corneal surface, and with his ophthalmometer measurements of the inequalities of the curvature of the eye were made. The perfection of the instrument showed, however, that though the anterior surface of the cornea was a large factor in the production of the defect yet the total astigmatism varied considerably from that of the cornea; it might be more or less, and the axes of the corneal and total astigmatism might vary. It became evident that other surfaces of the refracting media took part in the production of the defect, and the measure of the whole by means of retinoscopy was more accurate and useful than the measure of the corneal surface. In a recent monograph on *Blastigmatisme*,* by Drs. M. MARQUEZ and T. BUSTO of Madrid, there is presented a detailed discussion of these matters, and therewith a consideration of the value of correcting astigmatism by means of bicylindrical lenses, set at varying angles to each other so as to produce a great variety of fine corrections. The authors have worked out a series of tables which give the values, in spheres and cylinders, that result from these combinations.

Notes on Books

In *The Healthy Infant*† Dr. E. R. C. WALKER has given a very clear account for the intelligent mother of how to manage her child. Besides describing in detail the general principles of diet and hygiene, Dr. Walker has successfully shown the reasons for many of the measures advocated, and he includes a very good adaptation of modern psychological teaching for use in regard to the early period of life. It is possible to find fault with small, almost controversial, matters in certain sections—as, for example, the advocacy of one breast at a feed instead of both—but in general the presentation of teaching where there is room for a difference of opinion is scrupulously fair, and the intelligent mother should easily be able to make up her mind upon a course of action. It is a pity that while such elementary details as care of the nails receives mention, there is no discussion of what the mother is to do about the foreskin. Professor Charles McNeil has written a foreword commending Dr. Walker's book, and with what he says there we heartily agree.

A book which has proved highly popular with nurses is the *Complete System of Nursing*, by A. MILLICENT ASHDOWN; it has been reprinted eleven times since 1917. The author has now issued her book with certain additions and deletions as *A Complete System of Nursing for Male Nurses*.‡ For this purpose chapters dealing with diseases of women and children have been deleted and several illustrations have been added. The volume treats of the general duties of a nurse and the minor surgical and medical procedures which the nurse may be called upon to carry out—such as drawing off stomach contents, the testing of urine, catheterization, etc. The application of bandages, splints, extensions, etc., is fully treated. A chapter on the general observation of symptoms appears

* *Le Blastigmatisme dans la Pratique. Tables pour la Transformation des Verres Bicylindriques d'Axes Obliques en Verres Sphéro-cylindriques*. By M. Marquez and T. Busto. Second edition. Madrid: J. Cosano. 1933. (Pp. 55. 5 pesetas.)

† *The Healthy Infant*. By E. R. C. Walker, B.A., M.B., F.R.C.P. Edinburgh: W. Green and Son, Ltd., 1934. (Pp. 137. 3s. 6d. net.)

‡ *A Complete System of Nursing for Male Nurses*. By A. Millicent Ashdown. London and Toronto: J. M. Dent and Sons, Ltd.; New York: E. P. Dutton and Co., Inc. 1934. (Pp. xvi + 639; illustrated. 12s. 6d. net.)

to be particularly helpful. Medical nursing, with general descriptions of various diseases and the special points of attention required from the nurse in each, is treated with considerable fullness, and surgical nursing is similarly dealt with. Special chapters are devoted to ophthalmic nursing, nursing in diseases of the ear, nose, and throat, massage, medical electricity, the administration of drugs, and treatment of poisoning, and there is a brief, final chapter on diets and sickroom cookery. This book, like the manual upon which it is based, should prove very useful to nurses.

Mr. J. E. R. McDONAGH has now written the third volume of *The Nature of Disease Journal*.* Like its two predecessors, this is a substantial book of more than two hundred pages in which the author presents his original (one might almost say his unique) views on medical problems. The chief subjects discussed in volume iii are included under the headings "Rheumatism," "Women's Diseases," and "Infections from Within." There is also an editorial on the origin and nature of disease, and a chapter on the factors which determine the part of the body selected for attack in disease. The book will be added to the Library of the British Medical Association.

* *The Nature of Disease Journal*. By J. E. R. McDonagh, F.R.C.S. Volume iii. London: William Heinemann (Medical Books) Ltd. 1934. (Pp. 245. 10s. 6d. net.)

Preparations and Appliances

ANAESTHETIC SHIELD FOR USE IN MASTOID OPERATIONS

Mr. C. HAMBLIN THOMAS, F.R.C.S. (London, W.1), writes:

In mastoid and other operations on the ear, when the face is covered by the usual towel to shield the operation area, there is always a certain amount of discomfort to the operator and the anaesthetist. The latter has difficulty in keeping the patient's face under observation for the state of the pupils, etc., and a possible seventh nerve twitch of the face muscles, and the former is apt to have his towels and instruments displaced by the anaesthetist's manipulations. I have had made for me a simple and cheap metal shield, on the principle of the pattern I saw at the Manhattan Ear and Throat Hospital, New York.

Its method of use and its appearance when folded are illustrated here. When folded it is less than the size and about the thickness of this *Journal*, and it is easily packed. When in use it has sufficient rigidity to maintain its position. It can be sterilized, or it can be covered with a narrow sterilized towel folded around it. The lower plate is placed between the under side of the patient's face and a flat surface on which the patient's face (which has been turned well over) lies. The upper plate can be fixed by tapes or by towel clips engaging the upturned edge of the plate and the other towels around the patient's head. This upper plate acts as a small instrument table for the assistant.

The shield is made for me by Messrs. Arnold and Sons (John Bell and Croyden), 52, Wigmore Street, London, W.

VIONASE TABLETS

Vionase tablets (Wilcox, Jozeau and Co. Ltd., London) contain medicinal yeast (2½ grains per tablet), exsiccated ferrous sulphate (2½ grains per tablet), and small quantities of copper and manganese. They are recommended for the treatment of microcytic anaemia, and also for neurasthenia, debility, etc.

SATURDAY, SEPTEMBER 15th, 1934

THE ACTION OF INSULIN

In no section of metabolic research has more intensive work been carried out than in that of carbohydrate metabolism. The dramatic results obtained by the application of insulin to disturbed sugar metabolism need no comment at this stage. From the clinical point of view, one of the most outstanding results of insulin treatment is gain in strength, and this is true even when the patient is still not completely stabilized. From a condition of weakness, which may render the diabetic subject a pathetic figure, there gradually or sometimes rapidly is brought about an increase in muscular power which astonishes even the practised specialist in diabetes. There can be no doubt that insulin produces in some peculiar way a re-establishment of those processes in the muscles which lead to a normal capacity for work. This is undisputed, and yet the actual mechanism of this extraordinary result is entirely obscure. In a recent series of lectures Macleod¹ enters in some detail into the experimental work in this field, but, interesting as are the results of individual experiments, the problem is not very much nearer solution. The well-known researches of Dale and his collaborators, showing that in the eviscerated, decapitated, and glucose-perfused cat the injection of insulin produces an amount of glucose oxidation and glycogen deposition in the muscles exactly accounting for the disappearance of glucose from the perfusing fluid, are strongly criticized by Macleod. Whilst Dale's results were of a precision that appealed to the physiologist as apparently demonstrating an almost mathematical accuracy in a biological experiment, the clinician continued to wonder what the relation was between a very depleted and abbreviated cat and a normal or diabetic subject. Macleod, however, has again marshalled very strong evidence against the hypotheses and assumptions made in these perfusion experiments.

An outstanding source of error in the usual methods of calculation is the interpretation of the respiratory quotient. Cathcart some years ago insisted that the non-protein respiratory quotient is not a true oxidation quotient, and more recently Thunberg goes so far as to say that *none* of the oxygen used in general metabolism is found in the expired CO_2 , but that it is transformed to water. Investigation of the mechanism of insulin action in the intact animal is complicated by so great a number of accessory mechanisms that it seems almost impossible to expect any all-embracing conceptions to emerge. Macleod has reinvestigated and extended the *pigûre* experiment of Claude Bernard,

and has shown that carbohydrate metabolism is, at least in part, under the control of a centre or centres in the upper part of the pons. Interpreting his results, he considers that the process of glyconeogenesis is under the control of the parasympathetic, and glycolysis under that of the sympathetic. In conjunction with these purely nervous controls must be considered the demonstrated existence of a diabetogenic influence exerted by the anterior pituitary. This has been shown strikingly by Houssay, who found that removal of the pituitary before pancreatectomy prevented the development of typical pancreatic diabetes. In this connexion the association of glycosuria, and sometimes of true diabetes, with acromegaly must be kept in mind. There is also the delicately adjusted response of the adrenal gland to changes in blood sugar, directed to maintaining the latter at normal levels.

The recent striking findings of Ellis,² showing that patients with severe diabetes can tolerate enormous doses of glucose with doses of insulin not exceeding, and even less than, those necessary for stabilization on restricted diets, will give an important impetus to new ways of thinking on the pathogenesis of diabetes. Ellis's work will require extended investigation before interpretation will be possible, for he does not give in his paper any metabolic figures except those of blood sugar and qualitative urinary findings. These results, at any rate, dispose of the common notion that diabetes is entirely a matter of pancreatic dysfunction. The older view that insulin produces some change of alpha-beta glucose into a more active form has never been convincingly substantiated, but it is significant that so eminent an authority as Macleod should state that he has "a suspicion that insulin acts primarily on the glucose molecule and that the various physiological effects which follow its injection are secondary to this change."

RECONSTITUTED AND SOPHISTICATED MILK

The establishment of the Milk Marketing Board, and elimination of the "cut price" wholesale milk upon which considerable profits were made, has led to ingenious devices for replacing lost incomes. One of them which has recently been engaging the attention of the ever-vigilant guardians of the public health is a new device to enhance the value of skimmed milk. This can be bought on a large scale for something in the neighbourhood of a penny a gallon, and, if cream is added to it, the result is a fluid resembling genuine milk. Skimmed milk powder is a cheap article of commerce. If this is dissolved in water and cream added the resulting solution is something not easily distinguishable from the natural secretion of the cow. Sold at about a shilling a gallon, this product of cream and skimmed milk, or skimmed milk powder, yields an enormous profit. It is true that few would

¹ Bull. Johns Hopkins Hosp., February, 1934, p. 79.

² Quart. Journ. of Med., April, 1934.

accept it as real milk did they know the method of manufacture; but it is an extremely difficult matter to stop the traffic because, after all, this commercially made solution contains the ordinary constituents of cow's milk and passes the ordinary tests applied by the food inspector. The percentage of water and cream can be regulated to a nicety.

It must not be forgotten, however, that while the minimum fat content of milk as laid down in the Milk Regulations, 1901, is 3 per cent., the average fat content of genuine cow's milk is approximately 3.6 per cent. It is not surprising that the manufacturers of this product are concerned more with satisfying the legal minimum than with the preparation of a product as rich in fat as genuine milk. In consequence the artificial product often yields on analysis the bare minimum or little more in fat content. In other words, this product is 20 per cent. deficient in fat, and it has been pointed out that milk which consistently yields on analysis a fat content of 3 per cent. or thereabouts is open to grave suspicion. Now that attention has been drawn to this product food inspectors will be on the alert. There is one further loophole in the armour of the faker: the Milk and Dairies Order, 1926, states that the vessels used for the conveyance of skimmed or separated milk or for containing such milk at any time when it is exposed for sale must be marked with the words "skimmed" or "separated" milk. Naturally the persons concerned in the concoction of "pseudo" milk are not anxious to advertise their activities and in some cases the label has been omitted and the law broken. There is need, however, for tightening up the law in this respect because the Article of the Order in question does not clearly indicate whether churns containing skimmed milk are required to be marked as such when in a dairy and not exposed for sale.

There is a second device, to which the Medical Officer of Health for Kensington has drawn attention. This is the addition of skimmed milk to ordinary milk in contravention of Section 4 of the Milk and Dairies (Amendment) Act, 1922, which provides that: "No person shall add any colouring matter or water or any dried or condensed milk or any fluid reconstituted therefrom or any skimmed milk or separated milk to milk intended for sale, and no person shall, either by himself or by any servant or agent, sell, or offer or expose for sale, any milk to which any such addition shall be made." It was discovered that skimmed milk to which a quantity of cream had been added was being mixed with ordinary milk, the product being sold as genuine milk. The result of adding cream to skimmed milk in the proportion of one gallon of cream to sixteen gallons of skimmed milk is to produce a liquid with a fat content slightly below the minimum standard of the milk regulations. Genuine milk, of course, contains fat in excess of the proportion required by law. The result of the mixture of the two fluids is a product with a fat content above the legal minimum but less than the average obtained from genuine milk.

By this device is obtained, in addition to the legitimate trading profit, a further 9s. 6d. per churn of seventeen gallons.

Both devices—the reconstitution of milk from milk powder and the sophistication of milk by the addition of skimmed milk—are dishonest and undesirable practices. Present legislation is by no means adequate to deal with these new activities. The Kensington Town Council suggests that by new legislation the storage of milk powder on registered dairy premises should be prohibited; that dealers in skimmed milk should be registered and required to keep accurate records of consignments of skimmed milk arriving at or leaving the premises; that vessels containing skimmed milk should at all times be marked with the words "skimmed milk"; and, finally, that legislation relating to the addition of skimmed milk to milk should be amended so as to provide that milk includes cream. Great efforts are being made to improve the purity and quality of the most valuable of foods—milk. It is of first importance to stop the activities of persons who, in pursuit of personal profit, are placing on the market as genuine milk a liquid which is reconstituted or sophisticated.

CANCER CLAIMS

The recent publicity given by the Press both in this country and abroad to the alleged discovery of the cause of cancer by Dr. W. von Bréhmer, a member of the Reich Biological Institute in Berlin, cannot pass without comment. Dr. von Bréhmer¹ brings forward a hypothesis which rests on two series of observations—one physico-chemical and the other bacteriological. The first deals with the hydrogen-ion concentration of the blood, which he claims to be highly alkaline in cases of carcinoma, and the second purports to show that it is possible to isolate an organism from the blood and tumours of human beings and animals suffering from cancer, an organism which is only capable of active growth in an alkaline medium. From these observations he concludes that conditions which bring about marked alkalinity of the blood produce a suitable pabulum for the growth of the organism in question, which is responsible for the proliferation of the epithelium to form a cancerous growth.

In the first place, it would appear hardly believable that the extreme degrees of alkalinity of the blood claimed to have been observed by Dr. von Bréhmer—as great a pH as 8.2 is described by him in an earlier article²—would be compatible with the continuation of life, and it is certainly contrary to previous belief and experience. This matter has been taken up by Professor Heubner and Dr. Druckrey,^{3,4} who investigated the method adopted and have come to the conclusion published in the *Klinische Wochenschrift* that the palladium-hydrogen electrode hitherto used in the investigations

¹ von Bréhmer, W.: *Med. Welt*, August 25th, 1934, No. 34, p. 1179.

² *Idem*: *Ibid.*, December 9th, 1933, No. 49, p. 1737.

³ Druckrey, H.: *Klin. Woch.*, July 14th, 1934, No. 28, p. 1027.

⁴ Heubner, W., and Druckrey, H.: *Ibid.*, September 8th, 1934, No. 36, p. 1284.

gives results which are so wholly inconsistent that no correction factor is capable of making them reliable. If this is so it is clear that the whole of the alkalinity theory is open to very grave doubts.

In regard to the organism isolated, Dr. von Brehmer gives an elaborate and lengthy description which forms the greater part of his publication. Its morphology appears to be highly complicated, and it only assumes a bacillary or "tubular" form in the blood when the latter is alkaline, or in a special highly alkaline culture medium. The life-cycle is elaborate, and no fewer than seven stages are described. In alkaline broth it grows as a pellicle, is motile, and forms spores under unfavourable conditions. When growing actively some forms break up and discharge fine granules, which are capable of regenerating into the tubular form. In acid broth it breaks up into minute bodies, which are filter-passing and which vegetate when returned to an alkaline medium. With such an elaborate morphology it is not surprising that Dr. von Brehmer reserves for a future date the placing of his organism in an ordered classification, but disappointment must be expressed at seeing in the text of his article published in the *Medizinische Welt* large-scale drawings containing detail almost, if not quite, beyond the limits of microscopical visibility, and yet not seeing a dark-ground photomicrograph of sufficiently high power or definition to show any detail.

When consideration is given to the significance of such an organism, many questions arise which require satisfactory answers before its connexion with the aetiology of cancer can be accepted. First, there is the question of contamination during manipulation. Professor Schilling⁵ has carried out isolation experiments on the same lines and claims to have obtained similar organisms with complicated morphological forms. It is not to be suggested that any but the most careful manipulation was employed in either case, but at the same time bacteriologists will agree that there is a certain crudity in obtaining blood for cultivation from a finger prick and in grinding up a portion of a tumour in a mortar with saline solution and transferring a copious inoculum of the emulsion for cultivation in a fluid culture medium, the technique for both of which procedures is described. Then there is the question whether the tumour may not be harbouring some non-pathogenic organism. It is well recognized that in dealing bacteriologically with tissues it is not uncommon to meet with organisms of one kind or another which have invaded the tissues but which have no aetiological significance. Further, it does not appear that the most elementary of all questions has been satisfactorily answered or discussed—namely, whether the organism is constantly found in cases of cancer and in no other conditions. There is no information given as to how many cases have been investigated or from how many cases the "tubular" form of the organism has been isolated; nor is there information as to whether the organism has been sought for in, for example, lymphadenoma or the granulomas—conditions which

might well serve as controls. Lastly, there is so far no real evidence that a pure culture of the organism will reproduce the condition in animals. Dr. von Brehmer claims that it does do so, but reserves this most important point for future publication.

That Dr. von Brehmer and his associates have been carrying out their work for many years is well known, and last year, from information received, it was expected that an important communication would be made at an early date. It was hoped that such proof as was wanting would become available. Careful perusal of the data must, however, point in one direction only—namely, that the highly alkaline condition of the blood described in cancer patients is a myth, and that the idea that the organism isolated, whatever it be, acts by virtue of its ability to thrive only in alkaline medium is therefore irrelevant, and, further, that there is so far no proof forthcoming that it is a factor in the aetiology of cancer. It seems highly probable that the present claims will sink into obscurity, and, like many such claims in the past, will leave no impression on cancer research. Let it suffice to add that information received from the recent medical congress at Frankfurt indicates that the many eminent scientists present there, who heard the communications and also saw the slides and photographs exhibited, were entirely unconvinced.

Cancer "cures" and the alleged discoveries of the cause of cancer have been flooding the world of late years, especially in more recent months, since the taboo of the word "cancer" has begun to disappear. It is no exaggeration to say that during the last decade more than 500 such "cures" or "discoveries of the cause of cancer" have been investigated. It is true that the majority of these are frivolous in the extreme, but a fair proportion are built upon a basis of fact, and who is to say there is nothing in them? Experience has shown, however, that any real advance in our knowledge concerning cancer is obvious and credible from the start, and that those theories and hypotheses which, when fully examined, are found not to be based on sound argument and accurate and controlled observations have invariably fallen to the ground. The time has come for the public to be educated to think of cancer as they think of other ills, and not to consider it to be a thing unclean and not to be discussed. The greatest fear is the fear of the unknown, and knowledge regarding cancer and its nature largely dispels that fear of falling victim to the disease which is so prevalent in the minds of the community. At the present time the greatest hope of safety lies in early diagnosis. Fortunately, early diagnosis can be made with little difficulty in those forms of cancer which are the most common. It only requires the co-operation of the public to bring the patient and the doctor together in the early stages to effect a permanent cure in 50 per cent. of these more common forms. Let us educate the public to become aware of the problems of cancer and of the stages already reached in investigation and treatment, rather than let them catch at any straw in the shape of alleged cures which may drift their way.

INFANTILE CONVULSIONS

An association of general practitioners in France, under the name of *Assises Nationales de Médecine Française*, was founded to study in the everyday life and experience of its members various problems which could only receive a fragmentary type of investigation at the hospitals and clinics. A recent meeting dealt with the subject of infantile convulsions, and the discussion has been summarized in an article by Dr. P. Hartenberg.¹ It is pointed out that there are at least four schools of thought on convulsions in infancy: one holds that all such fits are epileptic, with the same aetiology as in adult life; one denies this view and thinks convulsions have a relatively banal importance without any relation to epilepsy; one holds that the underlying cause in all cases is tetany; and a fourth doctrine admits the possibility of all three preceding views. While the congress did little to elucidate this fundamental problem of causation it reached agreement on many points. It was reported from every area that there has been a great diminution in infantile convulsions in recent years, and that the actual fit must be regarded as a symptom of some more radical malady. The list of existing causes contains such well-known disturbances as fevers, gastro-intestinal infections and parasites, dentition, meningo-encephalitis and birth trauma (including asphyxia), while a familial predisposition was also noted in many instances. Syphilis was admittedly not as common as has been previously taught, while an alcoholic heredity is rarer than heretofore. In general the assembled practitioners thought that spasmophilia was an unusual factor in convulsions. It was agreed that the immediate prognosis is better than formerly, there being fewer fatal cases; but as to the eventual prognosis, especially concerning the possible development of epilepsy in later life, there was difficulty in reaching agreement as to the necessary criteria for prophecy. The proportion of all infants with fits who develop mental deficiency, paralysis, or epilepsy was variously put between 1 and 10 per cent. Dr. Hartenberg expressed a personal view by stating that the only guiding line is the presence or absence of a cerebral lesion. Another recent review² of the causation of convulsions in childhood by Dr. M. Peterman approaches the subject from a different aspect, and the conclusions have a bearing on the special period of infancy. The author has reviewed 500 cases in children brought to him in hospital or private practice for fits in the past ten years. The percentage distribution is as follows: epilepsy (idiopathic), 33; acute infection, 22.8; cerebral birth injury or residue, 15.4; spasmophilia or tetany, 13.6; miscellaneous, 8.8; and cause unknown, 6.4. Taking the period of infancy in more detail, Dr. Peterman shows that with six to thirty-six months as the age of onset acute infection heads the list with nearly 30 per cent., and spasmophilia is next with 22.4 per cent. His cases have been very fully analysed, with investigation of the blood chemistry when necessary, so that in this series tetany looms larger than in the French report. "It is only when the convulsions recur," he writes, "and after various unrelated stimuli and when all organic lesions are excluded, that the diagnosis of idiopathic epilepsy is

made." With this strict method of diagnosis Dr. Peterman is able to select three cases in the first month of life and a further five between one and six months of age as definitely epileptic. It is obvious, therefore, that although the percentage of such cases in the whole series is small, the occurrence of epilepsy among babies with convulsions cannot be excluded, and time must elapse before a final statement is made. A conclusion drawn by Dr. Peterman may be quoted to summarize the whole matter: "It is obvious that a convulsion is only a symptom, the final explosion of a complex reaction, the trigger mechanism of which may be a number of factors. . . . I wish simply to point out that there are certain disease entities which create in a patient a susceptibility to the convulsive state." While disagreeing in detail the French and American views are united on this point.

CHEVALIER JACKSON AND ENDOSCOPY

Killian has been called the "Father of Bronchoscopy," and, as the title indicates, he originated endoscopic methods upon which all later work has been founded. There is, however, no one either in the past or in the present who has contributed so much to the advancement and development of endoscopy as Dr. Chevalier Jackson. When *Peroral Endoscopy and Laryngeal Surgery*, completed in 1914, was published in 1915, it seemed as though no further territory remained to be explored and conquered by the endoscopic method, to such perfection had its technique been brought by Dr. Jackson and his staff. That book will always remain a milestone in the history of laryngology and a treasured possession of the fortunate, but when Dr. Jackson, in collaboration with his son, presents, twenty years later, *Foreign Body in Air and Food Passages*¹ it is interesting to endeavour to trace in what direction subsequent advances lie. The book in question makes no attempt to cover the whole field of endoscopy, but it is in the localization and removal of foreign bodies that the great triumphs have been won, and it is here shown how close the collaboration between the radiographer and the endoscopist must be. The sixteenth volume of the *Annals of Roentgenology* is much more than an atlas of x-ray pictures, which is all that it claims to be. Selected from a study of 3,000 cases of foreign body in the air and food passages, in order to illustrate the different pathological effects produced, the difficulties in finding opaque foreign bodies, the methods of recognizing the presence of non-opaque foreign bodies, the necessity of lateral in addition to antero-posterior views and sometimes of views from intermediate angles, and the possible errors in localizing foreign bodies which are plainly visible, the pictures, with the comments and the lessons which they teach, are an endoscopic education in themselves. The chapter at the end on fluoroscopic endoscopy for removal of foreign bodies which are endoscopically invisible shows how close and perfect this collaboration can be, and with what ingenuity the latest model of biplane fluoroscope had been constructed. Figure 137 and those immediately following need no comment beyond the simple statement that a bar pin is shown deep in the lower lobe of the right lung. The

¹ *Presse Méd.*, June 2nd, 1934, p. 885.² *Journ. Amer. Med. Assoc.*, May 26th, 1934, p. 1729.¹ Chevalier Jackson and Chevalier L. Jackson: *Ann. of Roentgenol.*, vol. xvi. New York: Paul B. Hoeber, Inc. 1934. (Pp. 265; 236 figures. 12 dollars.)

case was published as beyond the limits of bronchoscopy in 1907, the patient being a woman then aged 18. In 1930 extensive pathological changes were seen to have developed in the intervening twenty-three and a half years. Yet the pin was removed in two and a half minutes from the patient at the age of 43—a demonstration of the progress made in the technique of bronchoscopy. That foreign bodies hidden in the extreme periphery of the lung, even in the costo-phrenic angle, can now be removed endoscopically provided that the skill, the equipment, and the collaboration are available seems to leave nothing fresh to be accomplished in the art of removing foreign bodies.¹ Future advance seems to be in the application of endoscopic methods to the treatment of morbid processes, but it remains for the few to whom opportunity is given to maintain the exacting standard which Dr. Jackson has set.

THE STUDY OF ANIMAL BEHAVIOUR

Several of the papers presented to the British Association at its meeting in Aberdeen, and of the discussions following thereupon, have emphasized the fact that the results of scientific analysis, especially in physics and physiology, must be taken simply for what they are, and not regarded as ultimate realities by a summation of which the whole, particularly the organic whole, can be reconstructed or explained. In biology, for example, it is found to be essential to study the organism as a whole and not simply its component parts or systems. This tendency of present-day science is, in fact and in effect, a harking back to common sense. On August 25th last (p. 361) we noticed an important book entitled *The Behaviour of Animals*, by Dr. E. S. Russell, in which this point of view in relation to its subject was admirably expounded and illustrated. In his presidential address to the Section of Zoology Dr. Russell made an excellently clear and reasoned statement of the same thesis. It was a noteworthy utterance to which the attention of all who are interested in the teaching or the study of biology and physiology should be directed. He contests alike the dualism of mind and matter, the mechanistic explanation of all physiological processes, and the underlying assumptions of the stimulus-response theory of animal behaviour. It is necessary to get back from Descartes to Aristotle. "Instead of being the most concrete of realities, both matter and mind are highly abstract concepts, the product of the reflective intelligence working upon the data of immediate experience. There is given in individual experience only the perceiving subject and his objective world. This dualism does not correspond with the dualism of matter and mind." The complete phenomena of life are shown only by individuals or organized unities. Moreover, "all living things pass through a cycle of activity which normally comprises development, reproduction, and senescent processes leading to death. The life-cycle is in each species a definite one, passing through a clearly defined trajectory, admitting of little deviation from normality." The behaviour of a living thing is, therefore, the activity of the organism "as an intact and unitary whole," and is directed towards an end, the completion of the normal life-cycle. This directive-

ness need not be consciously purposive, but it shows a certain measure of adaptability, and often the power of learning and profiting by experience. The "plain tale" of animal behaviour, as Professor Lloyd Morgan has recently called it, must start by direct observation of the animal in its natural surroundings, and should be continued in experimental conditions which approximate as nearly as possible to the normal; and the whole life-cycle of activity, not merely isolated parts of it, must be regarded as the primary thing. Analysis is justifiable and useful but lets slip the essential thing, the continuity and directness of actions taken as a whole. "A very great part of the behaviour of animals is response to needs (or deviations from normal) and not to direct external stimulation. . . . A good deal of what ranks nowadays as experimental biology is not biology at all, but physico-chemical research carried out on organic systems with complete disregard for the distinctive characteristics of such systems." Similarly, Dr. Russell points out, though we cannot know exactly what the quality of an animal's perception is, its response is not usually to separate physico-chemical stimuli, but to the perceptual field as a whole or to relations, patterns, or general images. This method for the study of animal behaviour is likely to be the method of the future and must have very important reactions not only upon the relation of biology to medical education, but even upon the teaching of human physiology.

MEDICAL TERMINOLOGY, INTERNATIONAL AND NATIONAL

A correspondent of the *Münchener medizinische Wochenschrift*,¹ after a passing reference to the present precarious position, in the school curriculum, of the study of Latin—already eliminated in some of the countries speaking a Latin-derived language, and in others threatened because of its alleged uselessness in comparison with the time taken up by its study—alludes wistfully to the happy position enjoyed, in the Middle Ages, by the possessor of a working knowledge of the Roman tongue. For this reason, rather than for the stock reasons which are put forward for the retention of instruction in Latin—the intellectual exercise, the enlargement of the intellectual horizon, the assistance given in mastering modern languages of Latin derivation—the writer is all for keeping Latin teaching alive. Possessing eight modern languages, he nevertheless finds it impossible to read a large proportion of modern scientific literature. Three or four centuries ago all that was of value would have been accessible to him after the learning of one foreign tongue only; but scientific literature, unfortunately, becomes nowadays less cosmopolitan and more "nationalistic." The nationalist quality of terminology in German medical literature has indeed become a source of difficulty not only to the investigator who seeks to refer to the work, often most valuable, of German authorities in similar fields, and to the medical journalist in particular, but also, as it would appear from a note in the same issue of the *Wochenschrift* by Professor Enderlen of Stuttgart, to the German medical man himself. Enderlen, reading a review of a surgical treatise, noted four "Verdeutschungen" which left him—a good German, as he says—in doubt concerning

¹ Chevalier Jackson and Chevalier Laurance Jackson: *Arch. of Otolaryngol.*, June, 1932, xv, 860.

¹ February 16th, 1934, p. 256.

the meaning of these "Germanizations" of anatomical (classical) terms. Further, as he slyly remarks, - a reference to a German-French dictionary convinced him that a French medical reader would be equally at sea. The retention of Graeco-Latin forms of nomenclature is therefore recommended, as simplifying international, and even also national, understanding. In an appended note the editor of our contemporary lends the weight of his authority to the retention of classical terminology. Nevertheless, he is against the incorporation, in German medical literature, of a jargon of new foreign terms from contemporary foreign literature: if noteworthy, he thinks, they deserve translation into good German. He would even purge his country's archives of the French or English terms, such as "*défense musculaire*" or "*missed abortion*," which have already crept in and been accorded general understanding. It is with some regret, it would seem, that he rejects as Utopian the counsel that we should revert to Latin as the universal language of medical science: thus we might at once make the world-literature accessible at its sources to the educated person, and exclude from it the uneducated laity.

RED CROSS AND ST. JOHN

A wide range of activities is reviewed in the report for 1933 of the Joint Council of the Order of the Hospital of St. John of Jerusalem and the British Red Cross Society. Through the auxiliary hospitals for officers department, assistance was given to 256 officers, of whom eighty-one were new cases; 18,402 have now been helped since 1914. As in recent years tuberculosis was responsible for a large proportion of the claims, but relief was also afforded to surgical, medical, and convalescent patients by admitting them to the hospital at Brighton. Ministry of Pensions patients are received on payment; others contribute towards their maintenance, while some who are destitute are admitted free of charge. Help has also been given to ex-officers who, while able to trace their illness to war service, cannot produce a continuous medical history which would establish their claim on the Ministry of Pensions. The cases now dealt with are usually in more advanced stages than has been usual hitherto, by reason of the prevalence of ill-health, failing employment, and insufficient food. Another department, the central bureau of hospital information, has been very active. Eleven memorandums have appeared relating to such subjects as accommodation for paying or private patients, financial arrangements for orthopaedic patients, the medical staffs of small general hospitals, particulars of consumption and cost of water supplies, and the provision of hospitals with milk. The 1933 edition of the now well-known *Hospitals Year Book* won general approval as a compendium of useful information about the various sides of hospital administration. The committee in charge of comforts, ward industries, and stores made 275 grants in response to applications from Ministry of Pensions hospitals and other institutions; about 450 men were enabled thus to receive training in handicrafts. Conveyance to entertainments was arranged for over 9,000 patients; since 1920 well over a quarter of a million have had transport without a single accident. The Emergency Help Committee has assisted 12,725 cases. Refunds of loans amounted to £4,440; the total repayments since

the inception of this scheme total £137,895—a sum sufficient to maintain this work on its present basis for more than two years. The home service ambulance committee reports that 120,343 patients were carried in the twelve months, some being invalids requiring treatment and others accident cases. There are now in the country 153 ambulances equipped by the committee, and 169 other ambulances affiliated to the service. Last year gifts were made of 157,000 books, 82,000 magazines, and 250,000 newspapers. Yet the demand by institution libraries grows greater still, and further gifts of this kind will be welcome.

THE GUTTADIAPHOT

Tests involving the examination of the blood in tuberculous patients are increasing in number, if not always in usefulness. The somewhat barbaric-sounding term of "*guttadiaphot*," signifying "the picture of a drop in transmitted light," cloaks a method of capillary analysis first introduced in Germany by Meyer, Bierast, and Schilling, and consists in placing drops of the patient's blood on specially prepared strips of blotting paper (divided into red, green, and blue squares), and examining the stains so obtained some hours later by direct and transmitted light. Certain features of colouring, outline, and consistency are found to be associated with abnormalities of the blood in systemic diseases. Piechaud, Dutrénil, and Guibert¹ give a very extensive account of the history, theoretical basis, technique, and applications of this method, with special reference to tuberculosis. If certain precautions in the carrying out of the test are taken, the interpretation of the pictures obtained offers no difficulty with a little practice. The test is considered particularly useful in anaemic conditions, and is stated to be more sensitive than the Wassermann reaction, especially in treated cases. In pulmonary tuberculosis the results do not appear to be clear-cut or very helpful, but the authors found a direct relation between the results of the test and the temperature curve, and an even more striking one with the sedimentation rate. The positive results obtained are not entirely accounted for by the anaemia often found in consumptives. The test is recommended as a simple and ready means of detecting that "something is wrong" for the practitioner "in the country" to whom more complicated methods of examination are not easily available. A bibliography consisting of some fifty-five references is added.

At a medical meeting at Frankfurt a/M, held from September 2nd to 9th, under the presidency of Professor W. Kolle, the Paul Ehrlich gold medal was awarded to Dr. Walter Kikuth. At the age of 38 Dr. Kikuth has succeeded in performing an enormous amount of useful work culminating in chemotherapeutic discoveries of great importance. Atebrin and its specific action upon the malaria parasites, especially the subtertian form, was worked out by him by comparative studies on the malaria-like parasites of the canary and the Java sparrow. Dr. Kikuth is now the head of the chemotherapeutic department of the I. G. Farbenindustrie at Elberfeld in succession to the late Dr. Roehl. He is also attached in an honorary position to the Medical Academy at Düsseldorf. Dr. Kikuth was born in Russian territory at Riga and, after commencing his studies at Dorpat, he was able to complete them in Germany after the Russian revolution.

THE BRITISH ASSOCIATION

ANNUAL MEETING IN ABERDEEN

The 103rd annual meeting of the British Association for the Advancement of Science was held in Aberdeen from September 5th to 12th under the presidency of Sir James Jeans, who had been elected to the post left vacant by the death of Sir William Hardy. The Association had previously met in Aberdeen in 1859, when the late Prince Consort presided, and in 1885 under the presidency of Sir Lyon Playfair. A message from the King expressed his confidence that the investigation of the manifold problems confronting present-day scientists would continue to be productive of results which would benefit mankind. Professor W. W. Watts was elected to preside over the Norwich meeting next year.

PRESIDENTIAL ADDRESS

Sir James Jeans commented on the amazing changes in outlook which had occurred in the full half-century that had elapsed since the presidential chair had last been occupied by a theoretical physicist in the person of the late Lord Rayleigh, and compared the department of theoretical physics to a building brought down in ruins by a series of earthquakes. New facts of observation had wrecked previous conceptions, which were founded not upon the solid rock of ascertained fact but upon the shifting sands of conjecture and speculation. The fundamental mistake of the old-time physicist was that he had failed to distinguish between the half-truths of parables and the exact truth. Physical science obtained its knowledge of the external world by a series of exact measurements, or, more precisely, by comparisons of measurements. Knowledge of the external world must thus always consist of numbers and the synthesis of this knowledge be mathematical in form. The modern physicist accepted this implication, and distinguished between observable facts and pictorial parables. Space and time could no longer be classified as realities of Nature, and the generalized theory of relativity showed that the same was true of their product—the space-time continuum. This had destroyed the Newtonian conception of a rigid universe and the derived doctrine of mechanistic determinism. Modern theoretical physics set before itself the modest task of reducing to law and order the impressions which the universe made on the human senses. It was concerned with appearances rather than with reality, and the task of the physicist resembled that of the map-maker rather than that of the geologist or mining engineer. Theoretical physics had produced two maps—the particle-picture and the wave-picture. The first was a materialistic picture, catering for those who liked to see their universe mapped out as matter existing in space and time. The wave-picture had a determinist character, catering for those who asked the question: "What is going to happen next?"

After elaborating this point, Sir James Jeans came to what he termed the central and most surprising fact of the whole situation, which he thought would lead to most surprising changes in the views held of the universe as well as of the human race. The modern conception that a system of waves best depicted in a graphic form the knowledge gained of the constituents of the universe had revealed the central fact that this wave-parable had shown these waves to be Nature itself. The Nature studied was not objective, consisting of something perceived, but was rather the perceptions themselves. There was no clear-cut distinction between subject and object: they formed an indivisible whole which now became Nature. In the old physics the perceiving mind was a spectator merely; in the new physics it was an actor: the perceiver and perceived were interacting parts of a single system. The old physics seemed to indicate that freedom was an illusion; the new physics implied that this might not be so, and that it was possible to mould events to human desires and to live lives of emotion, intellect, and endeavour. Both materialism and matter needed to be re-defined in the light of the new knowledge.

The full-blooded matter and the forbidding materialism of the Victorian scientist had given place to a movement in the direction of philosophic idealism. Mind and matter, if not proved to be of similar nature, had at least been found to be ingredients of one single system. There was no longer room for the kind of dualism which had haunted philosophy since the days of Descartes. Photons were no longer to be regarded as single individuals, each going its own way, but as members of a single organization or whole—a beam of light. Biologists were beginning to state, though not very unanimously, that the same might be true of the cells of the body. It was conceivable also that the same might be true of the perceiving minds, and so human individuals might form ingredients of a continuous stream of life, even though regarding themselves as obviously distinct persons when viewed in space and time.

Defending scientific progress against the charge of causing unemployment in industry and wars, Sir James Jeans said that it was obvious that a country which fell behind in such advance would soon also fall behind in its industries, its economic position, its naval and military defences, and its culture. Labour-saving devices and what was termed pure science might ultimately lead to new trades and new popular demands, providing employment for vast armies of labour. A balance must be maintained, however; for a steady flow of labour-saving devices, with no accompanying flow of new industries to absorb the labour thus displaced, could only lead to unemployment and chaos in the field of labour. At present the want of balance tended towards unemployment, and the great need of the moment was for industry-making devices. Employment for millions of men had been provided by Faraday's electro-magnetic induction, Maxwell's Hertzian waves, and the Otto cycle, while the economic value of one scientist alone, Edison, had been estimated at three thousand million pounds. Unhappily, no amount of planning could arrange a perfect balance, but the throttling down of science would only crystallize the community in its present state with nothing to do but to watch its population increase, and shiver as it waited for the famine, pestilence, or war which must inevitably come to restore the balance between food and mouths, and land and population. Was it not, therefore, better to press on efforts to secure more wealth, leisure, and dignity of life for our own and for future generations, even though risking glorious failure, than to accept inglorious failure by perpetuating the present conditions in which these advantages were the exception rather than the rule?

HARDY MEMORIAL LECTURE

Sir Frank Smith, Secretary of the Department of Scientific and Industrial Research, paid a warm tribute to the work performed on behalf of the Department by Sir William Hardy in the last seventeen years of his life with special respect to the research into the transport and storage of foodstuffs. He described the way in which the Department's Torry Research Station at Aberdeen, founded by Sir William, was likely to help the fishing industry to regain its prosperity. The recent report of the Sea Fish Commission had stressed the highly perishable nature of the herring. Those caught more than twenty-four hours before landing were known in the trade as "overdays," and were inferior in quality—a fact which led to the important industry of kippering, and partly explained why the kipper was the most popular form of herring with the public. The fish was smoked nowadays, as heretofore, over smouldering fires of sawdust, a process which was at the mercy of the weather, and depended largely on the craftsmanship of the smoker, the antiseptic substances in the smoke, the range of temperature, and the dampness of the drying atmosphere. Each of these variables had been separately investigated at the Torry Research Station, and a new type of smoking kiln had been designed to control them. With its aid any desired type of cure could be produced with certainty. Home waters were unable to cope with the demands of the market for good white fish, such as cod, halibut, and plaice, though there were now about 1,600 trawlers fishing from British ports and landing each year nearly 1,700,000

tons of fish. Far too large a proportion of the fish landed was stale. Mere chilling in crushed ice was ineffective, but the Research Station had found a possible way out in the form of freezing the fish in cold brine at a temperature of -20°C . The growth of bacteria was thus completely arrested, and if the fish was stored at this temperature it would keep perfectly fresh for three months.

Sir Frank Smith discussed the immense progress made in the science of refrigerating foods during the last fifty years. Thanks largely to the work of Sir William Hardy, it was now recognized that the biologist should formulate the conditions required for the satisfactory storage of various forms of foodstuffs, and that the engineer should then provide these conditions. In the case of meat, for example, deterioration was due to enzymes or organisms naturally present in the meat itself, and secondly to the growth of moulds and external bacteria. The first could be entirely prevented by cold, but the second depended on the initial contamination to which the meat had been exposed, unsaleability resulting when the bacterial population reached a density of over 30 million organisms in each square centimetre. The importance of cleanliness was therefore manifest, for freezing produced changes which were likely to damage the meat. This risk was negligible in the case of mutton, lamb, and pork, but rendered freezing as distinct from chilling unsatisfactory for beef. The work at the Department's Low Temperature Research Station had shown that at temperatures near freezing point a concentration of 10 to 20 per cent. of carbon dioxide so delayed the growth of micro-organisms as to double the life of the beef. Hardy and his colleagues had found that different kinds of fruit exhibited idiosyncrasies as regards preservation. It was largely the intolerance for cold shown by the British apple which accounted for the fact that for about nine months of the year the table apples in this country came from over-seas, although some of these were gathered at the same time as the home-grown apples. Sir William Hardy had solved this problem by storing the fruit in a definite percentage of carbon dioxide, while the temperature of the store was kept well above freezing point. This discovery had opened a new era in the storage of English apples, and there were to-day thirty-two such gas stores in this country with a total capacity of 7,000 tons. The rate at which these were being erected was rapidly increasing. The brilliant work which Hardy had inaugurated and directed had been of enormous advantage already, and it was still extending.

COLOUR VISION

Professor H. E. Roaf, president of the Section of Physiology, in an address on normal and abnormal colour vision, discussed the validity of the trichromatic hypothesis, the nature of the departures from colour vision in those with colour-blindness, and the nature of the colour-perceiving mechanism. He said that if it was to be taken as true that three types of sensory mechanism were sufficient to account for colour vision one of the four colours red, yellow, green, and blue must be due to stimulation of at least two of the other ones. For several reasons yellow had been chosen as the heterogeneous one. Experimental evidence was forthcoming that a red stimulus to one eye and a green to the other gave a sensation of yellow, this result being obtained even with lights from the spectrum. Since the unitary sensations yellow, white, and black could be built up from stimuli associated with other sensations, it was possible to reduce the number of data for colour perception to three, and there was no real objection to the trichromatic explanation of colour vision proposed by Thomas Young. Abnormal colour vision might be congenital or acquired; the usual form was congenital, and did not alter through life. The defect seemed to consist in a decrease in the ability to distinguish red from green, and the patients (hypochromats) distinguished fewer colours than the normal (euchromats). They were often described as having blue-yellow vision, or of distinguishing in the spectrum blue from not blue, whereas the normal person subdivided the not blue into red and green. Since yellow occupied the region between red and green,

the defect was most noticeable in the yellow region of the spectrum, especially in the milder degrees of the defect. The hypochromat seemed to have only two types of colour receptor organs, whereas the normal person had three. The threshold for light was not necessarily altered, and it was possible for hypochromats to see clearly through a filter which only permitted the passage of the red end of the spectrum. In fact, a hypochromat who could not see red geraniums among green leaves could distinguish the flowers as light objects against a dark background when looking through a red glass filter.

Professor Roaf thought that the trichromatic hypothesis implied, as stated by Young, the presence of three types of receptors linked with three groups of nerve fibres in the optic nerves. It did not seem likely that there were three photo-active substances which were acted on by the long, medium, and short wave-lengths of the visible spectrum; only one photo-active substance, rhodopsin or visual purple, had as yet been found. Professor Roaf added that his own work had led him to believe that the types of receptors which were stimulated by visible radiation were as follows: (1) one which was stimulated by all parts of the visible spectrum, and gave rise to a sensation of violet when stimulated strongly by itself; (2) one concerned with the not-blue aspect of vision of the hypochromat; and (3) one which functioned in normal vision, distinguishing red from not red. In some persons the activity of one of these types was reduced or absent, giving rise to varying degrees of defective colour vision.

NUTRITION AND DISEASE

In the Section of Physiology Professor L. S. P. Davidson read a paper on nutrition in relation to anaemia, and a joint symposium was also held with the Section of Agriculture on nutrition in relation to disease generally. Professor Davidson pointed out that in the last ten years there had been an unparalleled advance in knowledge regarding the relation of diet to blood formation. This had been the means of eliminating certain forms of anaemia completely, of bringing under therapeutic control others which were incurable, and of directing attention to others which had previously escaped notice. Before 1926 every patient with pernicious anaemia had died. To-day it was known that the essential cause lay in a failure of gastric secretion which prevented the patient obtaining from his food a principle which was essential for normal blood formation. Successful liver therapy had ensued. Of greater economic importance, owing to its great frequency, was the group of nutritional anaemias due to iron deficiency. Approximately 50 per cent. of infants and adult women of the poorest classes were anaemic. The principal factors were: (1) pregnancy, and loss of blood at the menstrual periods, leading to increased demands for iron; and (2) an iron-poor diet which failed to maintain adequate reserves to meet such eventualities. Dietetic therapy and the administration of iron salts rapidly and cheaply brought about a remarkable improvement in health, with a corresponding gain in economic efficiency and resistance to disease.

In the symposium Dr. J. B. Orr said that recent investigations had indicated that nutrition as determined by diet was now probably the most important factor affecting the health of the community. He suggested that the present generally accepted standards of health were too low. If the necessary measures could be taken to ensure that every member of the community had a diet which was fully adequate for health, the next generation would be endowed with a better physique, and be freed from much of the disease and indefinite ill-health which afflicted the present generation.

Professor J. J. R. Macleod said that the discovery of deficiency diseases had made great strides, but the most important problem awaiting elucidation was to determine to what extent more general diseases in man might be similarly related to nutrition. There was evidence that diabetes, anaemia, and goitre were nutritional diseases, and probably other maladies were attributable to faulty dietetic habits.

Dr. May Mellanby remarked that, as regards dental caries, which was almost universal in civilized countries,

at least an
in the 1970s
of in-patients in
out-patients 5,367,369.
and more than
at hospitals

schools. As yet there seems to be no definite movement one way or the other to show the effect of the recent consideration that has been given to the true function of the out-patient department. Reference is made to the movement for more pay-bed accommodation, and a short list is included of about a score of contributory schemes for paying or private wards, of which that of the British Provident Association is the most important, aiming to provide, by means of insurance, cover sufficient to meet hospital charges, with proper remuneration for the doctor. Other useful information concerns the manner in which about one hundred small general hospitals—no doubt representative—appoint their medical staffs. So far as their general wards are concerned, seventy-three of these have a restricted honorary medical staff, in which appointments are limited in number and candidates have to submit themselves for election; in eighteen others any practitioner in the area is eligible for membership of the staff; in five the senior posts are filled by visiting specialists (not local practitioners), but any practitioner in the area is eligible for membership of the staff, and in seven there is partial restriction—that is to say, residence within a defined area, but no restriction in number of staff appointed. Information as to their private wards is afforded by fifty-two of these hospitals. In twenty-four,

although there may be restrictions in the general wards, any practitioner in the area served is at liberty to treat his own patients in the private wards, and in the other twenty-eight the same conditions apply in the private as in the general wards.

GENERAL INFORMATION

A word should be said about the encyclopaedic character of this publication. If it is desired to know how many hospitals possess their own laundries, what the experience is with regard to the efficiency of synchronized clocks, how much hospitals pay for their milk, what methods are favoured for the disinfection of wards, how food is commonly conveyed from kitchens, the number of times the lighting of operating theatres failed at certain hospitals, the steps taken to prevent cripples from slipping on hospital floors, the conditions governing the use of the premises of hospital supplies of radium, the bill for replacements of broken crockery, the weekly wage of hospital porters, the incidence of tuberculosis among nurses, the dates of foundation of the various hospitals, or particulars of the fourteen British hospitals on the Continent—these and a thousand other details are readily obtainable.

India

Pasteur Institutes

In the absence of any compendium of reports on the Pasteur Institutes of India it is excusable, though regrettable, that recognition of the excellent work therein accomplished year by year is not more widespread. The annual reports of some reach England from time to time, but mention of the activities of others is only to be found in the reports of Government medical officers, which are often very belated. The report has recently been received for 1932-3 of the Institute at Kasauli, which, with its various subsidiary centres, dealt with 15,118 patients in the twelve months, an increase of nearly 3,000 on the previous year. The period under review is regarded as being especially important, since it was the first in which the results accruing from researches covering several years could be given a practical therapeutical trial. It had been shown that large doses of antirabic vaccine were superior to small ones in preventing rabies, and that, as found elsewhere, the Paris strain of rabies-fixed virus had better antigenic value than the Indian strain. Consequently during 1932 the Paris virus alone was used in manufacturing vaccine, and a scale of dosage was devised which ensured a much higher average dose of vaccine for each patient than had previously been in use. The result was that the total number of deaths from hydrophobia was over 27 per cent. less than in any previous year since comparative statistics were available, and this in spite of the fact that the number of patients coming for treatment was much greater, indicating a distinct advance in the method of treatment. There were no cases of post-treatment paralysis. The annual report for 1932 of the director of the Pasteur Institute of Southern India at Coonoor is published with the twenty-sixth annual report of the Central Committee of the Association. Here also there has been a profitable decentralization of treatment throughout the Madras Presidency, the States of Mysore, Travancore, Cochin, and Pudukottah, and the Nizam's dominions. The daily attendance at the Central Institute has fallen, therefore, the figure for the year being 566. Three of these patients died from hydrophobia after a complete course of treatment and one during it, the mortality rate being 0.7 per cent. The Paris-fixed virus was in use throughout the year. Antirabic virus

was issued for 10,350 patients in the various centres; there were thirty-four deaths, and a mortality rate of 0.38 per cent., the lowest mortality rate on record at this institute, the decline being tentatively attributed to the use of the Paris virus, with the proviso that definite conclusions cannot certainly be drawn yet. During the twenty-eight years of existence of the Coonoor Institute 34,827 patients have been treated there, with a total mortality rate of 1.11 per cent. The success of the antirabic treatment is indicated by the steady increase in the demand for supplies. The Coonoor Institute serves 107 centres in charge of medical officers specially trained in this therapy, and courses of instruction, lasting seven consecutive days, are held from time to time. Particular stress is laid in these courses upon the practical side of the work, with the result that the difficulties in looking after so many out-centres, and especially in securing accurate statistics, have been greatly minimized. Reference to the work of the Pasteur Institute at Patna and the antirabic centre at Cuttack appears in the annual return for 1932 of the civil hospitals and dispensaries in Bihar and Orissa, which has been prepared by Colonel L. Cook, I.M.S., inspector-general of these hospitals. An arrangement has been effected with the Patna city municipality to provide suitable accommodation near the Institute for patients and their relatives coming for antirabic treatment. The vaccine can also be supplied by civil surgeons on requisition for patients not attending the Institute. During the year under review 4,112 patients attended at the Patna Institute, as compared with 3,626 in the previous year. The corresponding figures for the Cuttack centre were 366 and 287.

Medical Training of Women in the Punjab

In the annual report for 1932 on the working of hospitals and dispensaries in the Punjab, Colonel D. P. Goll, Inspector-General of Civil Hospitals, states that the number of girls seeking admission to medical colleges and schools is rapidly increasing. The accommodation in the existing institutions is very limited, and many candidates have to be rejected. It has for some time been proposed to establish a separate medical school for women at Lahore, but so far no steps have been taken. The Punjab Medical School for Women, with which is incorporated the Women's Christian Medical College for Women at Ludhiana, was hitherto the only institution on which

the Province depended for its supply of women doctors required for the charge of hospitals and dispensaries for women. To meet the growing demand among women for medical education of the degree standard, the system of co-education was introduced by the King Edward Medical College in Lahore in 1929, and extended to the Amritsar medical school in 1932. Up to ten places are reserved annually for women students in the former, and at the latter school the number has now been raised from ten to fifteen. The co-education system is reported to be working well. A large number of Punjab students are being trained in the Lady Hardinge Medical College at Delhi. In the year under review a noteworthy feature was the provincializing of the Lady Aitchison Hospital at Lahore. In Attock the Anant Ram Zenana Hospital was opened at Tallagang; the women's section of the Campbellpur civil hospital was placed in charge of a woman sub-assistant surgeon, and a travelling woman assistant surgeon was appointed for the district. In the Province there are now forty-four separate hospitals for women, and twenty-one sections for women in other hospitals, with women doctors attached to them. It is regretted, however, that the scheme for the provision of a women's hospital under a woman assistant surgeon at every district headquarters, and of a section for women at most of the tahsil headquarters hospitals, under a woman sub-assistant surgeon, is unlikely to be realized for a very long time, owing to the financial situation. Special efforts are being made to increase the number of Indian hospital nurses and of trained midwives, particularly in rural areas. In 1932, moreover, an Act was passed to provide for the registration and training of nurses, health visitors, midwives, and dais, and incorporating a Nurses Registration Council. The Punjab Central Midwives Board continued to supervise the training and examination of midwives, whose number is steadily growing.

Bombay Plague Epidemics

In 1932 there was a sharp increase in the plague mortality rate in the Presidency of Bombay, and this circumstance has caused Major A. Y. Dabholkar, I.M.S., Officiating Director of Public Health, to discuss recent epidemics of this disease in the course of his report on that year, which was otherwise a very healthy one, apart from a rise in small-pox. Since 1917, the year in which the highest mortality (162,874) was registered, plague has been decreasing in the Presidency, progressively on the whole, but showing well-marked exacerbations in certain years. In 1923 the deaths were 33,741, but in 1930 they had fallen to 5,026, and in 1931 to 3,506, so that the rise in 1932 to 14,446 was hardly expected, although it was generally thought that there might be some increase. The worst affected district was Belgaum, with a death rate of 4.38 per 1,000 of population, and followed by Satara, with a corresponding rate of 3.09. Sind escaped entirely, and Gujarat, with the exception of Surat and Kaira, was almost free. In the southern registration district, where the heaviest mortality occurred, the epidemic curve began to rise in August, 1931; steadily increased until January, 1932, with an uninterrupted fall in the ensuing four months; rose from June onwards; and reached a peak in December. The curve followed the usual course, the off season for plague in this district generally covering April, May, and June. Rat destruction campaigns were actively conducted. A significant indication of their value came from Bulsar in the northern registration district, where rat destruction was continued into 1933. At the time of reporting in that year there had been no outbreak of plague in that town, hitherto much affected, or in any of the neighbouring villages, although the time for its expected recrudescence was then

coming to an end. To combat the epidemic eleven medical officers were appointed on plague inoculation duty in the Presidency. The total number of persons inoculated in 1932 was 417,657, as compared with 112,025 in the previous year. Medical officers in charge of hospitals and dispensaries as well as private practitioners co-operated actively in the campaign. A statistical table of the number of deaths from plague since 1911 is given in the report. In the first year the figure exceeded 100,000, and it is apparent that this disease is gradually being brought under control, despite the occurrence of occasional epidemics, the mortality in which is definitely diminishing. Figures are also given showing the immunity conferred by inoculation, the popularity of which is increasing with the spread of knowledge. The destruction of rats is being energetically pursued. Of sixteen examined in Bulsar eight were found to be infected, whereas in Bombay City only 691 were infected out of 272,230 examined.

England and Wales

Queen's Institute of District Nursing

A statistical report has been compiled of the midwifery cases undertaken by Queen's nurses and village nurse-midwives working in connexion with the Queen's Institute of District Nursing during 1933. The former numbered 1,000, an increase of fifty-one, and the latter 2,855, an increase of forty-one. A total of 64,144 cases were attended; this represents a decrease on last year's total, but it is partly accounted for by the fact that particulars of cases in Cumberland are not yet available; these were about 900 last year. Medical aid for the mother was sent for in 31.5 per cent. of the cases and in 5.4 for the infant. There were 4,553 forceps cases, a percentage of 7.1. The number of maternal deaths was 145, of which thirty-eight, or 26.2 per cent., were primiparae, and thirty-eight had had five or more previous pregnancies. This mortality rate is 2.26 per 1,000, as compared with 2.1 in 1932 and 1.7 in 1931. The rate is 2.3 per 1,000 in urban districts and 2.2 in rural districts. These figures represent 58,946 cases in England, with a maternal mortality of 2.3 per 1,000, and 5,198 cases in Wales, with a maternal mortality of 1.9. The following table shows the causes of these deaths for the years 1933 and 1932.

	No. of Cases	1933	1932
		Per cent.	Per cent.
Sepsis	49	33.8	28.5
Accidents of labour...	37	25.5	29.2
Eclampsia	4	2.8	11.2
Embolism	20	13.8	6.3
Complications	35	24.1	24.3

Sepsis occurred in eighteen primiparae and in nine multiparae of five or more pregnancies, while accidents of labour numbered six in the former and fifteen in the latter. The percentage of primiparae in the series as a whole was 23.3. It is reported that ante-natal supervision continues to improve, although in many cases too few visits have been made during the last two months of pregnancy. Of the forty-nine deaths due to sepsis, seven occurred in forceps deliveries, in ten there was ruptured perineum, in six abortion had almost certainly been attempted, and four cases were infected by midwives. The thirty-seven accidents of labour comprised twenty-six of haemorrhage (including five cases of placenta

prævia, and seven of placental difficulty with manual removal in two instances), two cases of ruptured uterus, and nine of shock and cardiac failure. Cases of eclampsia declined from sixteen in 1932 to four in 1933, but there was a rise as regards embolism from nine to twenty. Of the embolism cases six had been delivered by forceps, five had histories of circulatory or cardiac troubles, and one patient was an alcoholic primipara. From several sources reports have been received of deaths caused by lowered vitality and lack of resistance to complications. The patients were not able to obtain sufficient nourishment during pregnancy, and some were living in overcrowded or otherwise unsatisfactory homes. In thirty-eight instances poverty-stricken homes were specifically mentioned. In one area it was stated to be difficult to obtain additional nourishment for expectant mothers on any but medical grounds, and it is submitted in the report that this should be available whenever the family income is insufficient to meet the added requirement of the mother during pregnancy. The number of maternity nursing cases (doctor engaged, midwife acting as maternity nurse) was 28,015, a decrease of 1,557 on the figure for 1932. There were 133 maternal deaths (4.7 per 1,000).

Health Work in Warwickshire

In a comparison of the more important statistical results for the year 1933 with those for the previous thirty years, Dr. Hamilton Wood, county medical officer of health for Warwickshire, points out that the birth rate for the year under review (13.71) is the lowest ever recorded in the county. He adds that if this fall continues, as it has done progressively since the high post-war rate of 1920, the time will soon be reached when the death rate, with its tendency to rise, will surpass it. The birth rate for England and Wales in 1933 was 14.4. There are nine ante-natal clinics at work in the county, but it is calculated that this service reaches only one out of every five expectant mothers who engage midwives for their confinement. Clinic provision would have to be doubled, therefore, to allow a substantial number of midwives' cases to have the advantage of medical ante-natal supervision. Since, however, there would still remain many expectant mothers in rural areas who would be unable to take advantage of this provision, Dr. Hamilton Wood considers that the question of introducing a domiciliary medical ante-natal scheme (as recommended in Memo. 156 of the Ministry of Health, 1930) might well be brought up. He remarks that a scheme of this kind is already operating in a number of county areas, and would appear to be the only practicable means of reaching the majority of expectant mothers engaging midwives for their confinements. Any such general practitioner service should not be in substitution for but in addition to the clinic facilities already provided in the more populous parts of the county. The county council has now in operation a scheme for compensating midwives in necessitous cases where the person engaging a midwife is unable to pay her fee, or where a midwife loses the whole or part of her fee in consequence of the patient's removal to hospital. It also provides compensation in cases where a midwife suffers financial loss as a result of suspension from practice owing to her being a possible source of infection. As regards rural water supplies, Dr. Hamilton Wood urges the importance of rural district councils discarding the parochial outlook and utilizing the resources of the district as a whole to fulfil a duty which in some cases has been sadly neglected for very many years. He adds that the financial side of the question should not be allowed to weigh too heavily against the advantages of a pure water supply, nor should the fact that a parish has a low rate of produce prejudice the rural district council in the fulfilment of its obligations.

The death rate from infectious diseases in 1933 was the lowest ever recorded, and no person died from typhoid fever. The pulmonary tuberculosis death rate rose slightly to 0.52, but the hope is expressed that this figure will fall in the next few years with improved housing conditions and better employment.

Ireland

Anthrax in a Slaughtered Cow

The medical superintendent officer of health, Dr. C. S. Thomson, in a report to the Public Health Committee, Belfast, illustrated the value of having only one abattoir in a city, and that one entirely under the municipality, with a fully qualified veterinary surgeon and staff in charge, supervised by the superintendent M.O.H. An animal was killed at Hillsborough, County Down, some twelve miles from Belfast, and was brought into the city to be sold to butchers for ordinary meat. The Belfast County Borough Council by-laws require that any meat brought into the city for that purpose must first be examined at the abattoir by the city veterinarian. On examination of this carcass the spleen was found to be somewhat enlarged. A smear was made, and the city veterinarian found that anthrax was present, although the carcass did not have the usual pathological signs of this condition. The carcass was burned, the meat inspectors were disinfected at the municipal disinfecting station, and all other necessary precautions were taken. Meanwhile, the city medical officer was informed that a man had been admitted from Hillsborough to the Royal Victoria Hospital with a malignant pustule, and investigation revealed that the patient was the man who had slaughtered the animal. The patient received prompt treatment and recovered. It is unnecessary to dwell upon the value of a system such as Dr. Thomson suggests.

Health of County Galway

In his annual report Dr. B. O'Beirne, county medical officer of health, states that 185 cases of diphtheria were notified in 1933, a decrease of six on last year's figures, the number of deaths being thirty-three, as against forty in the previous year. Fifty-nine cases are debited to the Galway urban area, although only eleven actually occurred there. The remaining cases were returned from the Galway Central Hospital, where the disease was endemic during the year, twenty-one being reported as "carriers." Efforts have been made to locate the source of the infection in this institution, and it now appears to be under control. The number of cases from the Galway rural district is high. This may be attributed to an outbreak in the Moycullen area, which became epidemic. As a result of investigation five "carriers" were discovered and isolated, and the outbreak was consequently checked. Tuam rural district has also a large number of cases, many of which occurred in the Abbey dispensary district; there are frequent occurrences of the disease in the Tuam districts. There have been no cases of typhus since 1930. Seventeen cases of enteric (or typhoid) fever were notified during the year—a reduction of four on last year's figures—with four deaths. There was no epidemic, the disease was sporadic, and in nearly all cases the source was attributed to the water supply. Ninety cases of scarlet fever were notified for 1933, as against 178 for 1932, and five deaths. Included in the sixteen cases debited to Galway urban area are two which were transferred from the general wards of the Central Hospital. Another case was that of a patient

from County Mayo, transferred from Bray, County Wicklow, where the disease was apparently contracted. Twelve cases of puerperal fever were reported in 1933, and twelve deaths. The six cases assigned to Galway urban area occurred in the maternity wards attached to the Central Hospital. Three cases of encephalitis lethargica were reported for the year under review, two being from the Galway urban area, and eighteen cases of erysipelas, four of which were transferred from the general wards of the Central Hospital. There is a disinfecting station, the property of the Board of Health, attached to the fever hospital, and a cleansing and disinfecting station, the property of the Galway Urban Council, at the docks. The latter is open to the general public, where baths, etc., are to be had for a small fee. There is a port sanitary authority and a port medical officer. In the case of the graver infectious diseases the ambulance takes the clothes to the fever hospital. A sack disinfectant was purchased by the Board of Health with a view to having disinfection and disinfection carried out on a large scale in outlying districts where there are epidemics of infectious diseases. The scheme, started in 1931, for active immunization against diphtheria is being continued in this county. In 1931 a total of 2,102 children received the full course of three injections, 1,206 in 1932, 1,607 in 1933, giving a gross total of 4,915. The reports from the various areas in which the scheme has been carried out have been most favourable.

County M.O.H. for Kilkenny

Commissioner P. J. Meghan, who is administering the business of the Kilkenny County Council, stated at a recent meeting that he had received a communication from the Local Government Department in reference to the appointment of a county medical officer of health. He said it was apparent, in view of the water supply and sewerage schemes in the different towns and villages in the county, and the housing surveys the Minister had requested, that a county medical officer was required. The question of school medical services was also of great importance. He proposed, therefore, to advertise for a temporary medical officer of health, at a remuneration of ten guineas a week with travelling expenses, to undertake the duties until such times as the Appointments Commissioners filled the permanent position. He had already made an order at the Board of Health regarding the new county school medical officer, so that 50 per cent. of the remuneration would be recouped from the grant for school medical services. With regard to the terms of the appointment, the Irish Medical Secretary wrote to the Commissioner pointing out that the temporary remuneration was altogether inadequate; he expressed the opinion that no candidate with adequate experience of public health administration would apply for the post at the remuneration offered, and, in the circumstances, it would be better if the Commissioner did not proceed with the temporary appointment. The temporary remuneration offered was £546 per annum with travelling expenses, as compared with £800 and travelling expenses for the permanent post. The Commissioner has now decided not to proceed with the temporary appointment.

"Gas in Housing and Slum Clearance," an illustrated pamphlet produced by the British Commercial Gas Association, serves as a reminder that town planning and slum clearance must be allied with the provision of an efficient and economical fuel if they are to succeed in bringing a better standard of comfort into the life of the working-class family. The pamphlet (No. 244 of "A Thousand and One Uses for Gas") can be obtained free from the office of the association, 28, Grosvenor Gardens, S.W.1.

CORRESPONDENCE

Pregnancy Diagnosis Station

SIR,—From a letter sent out as from the Pregnancy Diagnosis Station here to those medical practitioners whom it has served in the past it would appear that the station is closing down in Edinburgh and is reopening in London.

Actually this is not so. It is the case that, to my great regret, Dr. Wiesner, to whom is due all the credit for the inception and successful development of the station, is leaving this Institute and is moving to London, where he intends to continue his diagnostic and advisory work. But during the past five years the station has come to represent much more than the personal activities of one man; it has become a necessity to many practitioners, and though the man goes the service must continue. The laboratory here will not close down. At least it must continue to serve Edinburgh and the East of Scotland, and to do this it must serve a much wider area, for its efficiency must be largely determined by its size, and this must depend upon the number of clients. In efficient running, prompt reliable service, and low charges, several thousands of tests must be made annually. Its income must be sufficient to provide skilled medical supervision, an efficient technical staff, smooth routine, and, above all, sufficient data, for only then can the records possess any considerable scientific value. I have to hope, therefore, that this laboratory will be used by practitioners from all parts of Great Britain.

If the facts were better understood there would of course be room for more diagnostic laboratories than at present exist. It is irritating to recognize that even yet so very many practitioners either do not know that such a service exists in most of the larger cities, or, knowing, take no advantage of its existence. It should not be necessary to keep repeating that the tests now used yield an accuracy of not less than 97 per cent.; that pregnancy can be recognized as early as ten to fourteen days after conception; that the report on any given specimen can be dispatched after twenty-four hours, forty-eight hours, or five days, according to the particular test made; and that all that is required as test material is 50 c.cm. of morning urine.

The interest of this work is not commercial; it is to be found in the unusual and the exceptional; for in these cases is the seed of knowledge which, being disclosed, will contribute largely to the endocrine therapy of the immediate future.—I am, etc.,

Institute of Animal Genetics,
Edinburgh, Sept. 5th.

F. A. E. CREW.

Alkali Reserve in Asthma

SIR,—In his article in the *Journal* of August 18th (p. 299) Dr. Moll inclines to the opinion that in asthma there is a tendency to alkalosis. In support he repeats the well-known arguments about the rarity of asthma in certain diseased states known to be accompanied by acidosis. These are indirect and not convincing. More direct are McDowall's experiments on animals, in which bronchospasm was produced by alkalis, and Tiefensee's similar experiments. Tiefensee also claims, in support of an alkalosis, clinical proof based on biochemical findings. So far as I know these have not been confirmed.

Since the publication of his paper I have tried to find evidence of alkalosis mainly by the van Slyke method of determining the CO_2 combining power of blood plasma.

If this method, as carried out for me on seventy-two patients by Miss Jean Small, B.Sc., at Stobhill Hospital, is to be relied on, then the indication is quite frankly for an acidotic tendency. *There never has been the slightest evidence of alkalosis.* The normal range of figures for adults is given by Hawk as 53 to 80. Forty-nine patients gave a reading under 53—that is, nearly 70 per cent. gave a distinct indication of acidotic tendency. The readings may be summarized thus:

Under					
45	50	55	60	60 or over	
8	13	40	10	4	

Not only do these values speak for themselves but usually the more prolonged and severe the asthma the lower was the figure: as the asthmatic improves his alkali reserve rises and his eosinophilia usually falls. The four values of 60 and over were 61, 61.3, 60, 61, and their respective eosinophilia percentages were only 5, 4, 2, and 8: in all the asthma was slight and at infrequent intervals (weeks). On the other hand, a man with severe asthma and a 12 per cent. eosinophilia had the low reading of 40 for his alkali reserve, and died in status asthmaticus.

Further evidence in favour of acidosis is (1) the increase of ammonia-combined acid in the urine, as recorded by Oriel and myself, and (2) the effectual treatment of her asthmatic patients by Dr. Flora Innes of Vellore, India, who gives drachm doses of sodium bicarbonate in large draughts of water with fruit juice every two or three hours; the dyspnoea quickly disappears, as also, she claims, does the achlorhydria, which is such a frequent feature in chronic asthmatics. Oriel also recommends sp. ammon. aromat., a volatile alkali. Benefit from HCl is likely to be due not to meeting an alkalosis but to meeting the gastric subacidity. My findings in this respect agree with Bray's—48 per cent. hypochlorhydria, and 26 per cent. achlorhydria, a total of 74 per cent. with gastric subacidity.

It will be interesting to know the findings of other observers as regards the alkali reserve; and, if these confirm mine, to learn how those who champion alkalosis explain the low figures for severe asthma and the rise of the alkali reserve with clinical improvement.—I am, etc.,

Glasgow, Aug. 31st.

JAMES ADAM.

Is High Blood Pressure a Risk?

SIR.—In your issue of September 8th Dr. Thomas Robertson states that "anyone who has followed the trend of medicine for the last twenty years knows that . . . insurance companies are asinine." The ground for this statement, so far as I can gather, appears to be that they are chary of accepting, at ordinary rates, proposers with high blood pressure, in spite of the fact that some such cases live to a good old age.

Dr. Robertson agrees that "statistical investigations doubtless prove high blood pressures to be dangerous, but when it comes to a given patient there is no criterion whereby to judge the prognosis." If this is correct, surely the companies are justified in their attitude? Suppose they were offered a group of men aged 50, each with a systolic pressure of 200, but otherwise apparently healthy. They have every reason to suppose that the mortality experience in this group would be greatly in excess of the normal. Should they accept them at ordinary rates because some of them are likely to live long? Take a comparable example. If there were another great war, and 1,000 young soldiers wished to insure at ordinary peace rates, should they be accepted because some of them were almost certain to survive its dangers?

Until Dr. Robertson, from his observations on the trend of modern medicine, can teach the companies to differ-

entiate the good from the bad in a group of hyperpetics, they are likely to continue the "asinine" practice he seems to deplore.—I am, etc.,

London, E.C.1, Sept. 8th.

OTTO MAY.

SIR.—An *Epitome* paragraph entitled "The Prognosis for High Blood Pressure," which appeared in the *British Medical Journal* of February 6th, 1926 (para. 142), may interest your correspondent of August 25th, and seems worth quoting. It runs as follows:

R. Shiström (*Ugeskrift for Laeger*, November 19th, 1925, p. 1038), as the result of a study of over 300 cases of high blood pressure, finds that the average age at which this condition begins to make itself felt by the patient is 52 years, but that before this age the high blood pressure has existed for about ten years unobserved by the patient. The average age at death of this class of patient is about 62 years; thus from the beginning to the end of this condition there is apparently about two decades of life. Life may, however, last as long as twenty-five to forty years, and in twenty of the author's cases in which he kept in touch with the patient for ten to sixteen years the blood pressure was seldom or never below 200 mm. of mercury, although most of the patients were well and fit for work during the greater part of this time. The author insists that the patient whose high blood pressure begins at the age of 50 and lasts for twenty years or more can hardly complain that this condition has shortened his life, seeing that at the age of 70 he has already exceeded the average expectation of life. Factors affecting the prognosis unfavourably are an early onset of the high blood pressure, the coexistence of syphilis, and disease of the kidneys. In most cases it is impossible to decide whether the disease is progressive or not, and the physician is therefore not justified in giving a grave prognosis.

—I am, etc.,

London, S.W.11, Sept. 7th.

M.B., Ch.B.Ed.

Is the Taking of Blood Pressure a Risk?

SIR.—With reference to the letter by "M.S., F.R.C.S." in the *Journal* of August 25th, the answer, as I shall show, is in the affirmative when the blood pressure is being taken in elderly persons with signs of cardiac weakness. Here are two cases which occurred in my practice two years ago.

The first was a patient aged 74. He was a retired tradesman who had led a decent life except that he had for a time drunk too much whisky. He had gradually been getting weaker. He had no definite disease, although his heart showed signs of degenerative changes. I got one of our leading consultants to see him. After a careful and exhaustive examination he proceeded to take his blood pressure. We had only left the bedside one or two minutes when we were urgently recalled. We found the patient quite unconscious, his face blue, and after one or two gasps he was dead.

The second case was more appalling. He was an artist about the same age, who had led a perfectly good life. His condition was similar to the first case. I got the same consultant to see him. When we entered the bedroom he was sitting up in bed, and on seeing us he smiled and remarked, "I do feel a fraud, two doctors coming to see me and I feeling so well." These were his last words. While the consultant was taking his blood pressure I chanced to look at the patient. On calling the consultant's attention to the patient's discoloured face he released the instrument, but it was too late—he was dead.

In the first case the blood pressure reading was: systolic, 170 mm. Hg.; diastolic, 105 mm. Hg. In the second case, systolic, 140; diastolic, 120.

In both these cases death was certified as due to coronary thrombosis. As far as I know this danger has not been pointed out before.—I am, etc.,

West Bromford, Nottingham.
Sept 3rd.

W. HUNTER, M.D.

Haemorrhage from Peritonsillar Abscess

SIR.—Surely Mr. T. G. Wilson (September 8th, p. 491) misreads his "Cunningham" when he says that the tonsil is partly supplied by the descending palatine branch of the internal [sic] carotid artery. The internal carotid artery has no such branch, and the vessel named arises from the external carotid in the sphenomaxillary fossa.

In any case the contribution of the descending palatine artery to the tonsil is negligible when compared with that of the ascending pharyngeal artery, the facial artery by its ascending palatine and tonsillar branches, and the lingual artery by its dorsalis linguae branch.

Mr. Wilson's reason for ligaturing the common carotid artery would hardly appear valid unless associated adenitis made exposure of the external carotid too difficult, which does not appear to have been the case. The external carotid should be chosen for ligature, due regard being paid to the partly concealed and often very low origin of the ascending pharyngeal branch.—I am, etc.,

Canterbury, Sept. 10th.

THOMAS A. CLARKE.

SIR.—During recent renovations at my house, where Dr. J. H. Watson once had consulting rooms, the enclosed fragment was discovered among the deeper strata of *Fishery Gazette*s accumulated in the waiting-room. Apart from the intrinsic interest, it appears to have a bearing on a recent correspondence in your pages upon Haemorrhage from Peritonsillar Abscess.

"... a small monograph on *Inductive Reasoning as Applied to Anatomy*. The section upon the tonsil, for instance, points out that it is very like a lymph gland in structure; and, like a lymph gland, bleeds very little when cut. We should therefore expect to find a similar scanty blood supply from a single artery entering at a similar hilum where the veins emerge. It is exposed to the force of gravity and the tug of swallowing, both acting in the same direction.

There should therefore be, as elsewhere in the body, both a muscular suspension and a fibrous ligament to counter these forces. Abscesses are apt to form round its upper half, so that on the analogy of perineal and orbital suppurations there should be an areolar space surrounding it. The absence of these abscesses round its lower half would presumably show that it is there that our hypothetical muscular suspension is attached to the capsule. Dangerous bleeding may occur on one side and not on the other after the removal of identical tonsils by identical methods. Therefore this bleeding comes not from a vessel that supplies the organ, but from an independent one that may or may not be wounded, as the common facial vein may or may not escape injury in the removal of the glands of the neck. The bleeding is slow and persistent; such bleeding comes only from a vein. The narrow calibre and contractility of small arteries prevent any great loss of blood from them, just as their thick walls render them less liable than veins to perforation in surrounding sepsis."

"But, Holmes," I broke in, "bleeding after tonsillectomy is spoken of by all the authorities in terms of arteries, not of veins." Without even a glance in reply he continued, "We therefore have cause to suspect the common occurrence of a medium-sized vein, unaccompanied by an artery, running close to the capsule of the tonsil, in the areolar tissue between its upper half and the palate muscles. This vein would cause the persistent bleeding noted either after tonsillectomy or the bursting of a peritonsillar abscess, and controlled by ligature of the external carotid. It would also account for the disproportionate number of deaths under local anaesthesia for tonsillectomy; the unwary surgeon being liable to inject his drug almost directly into the heart."

At this point I began to wonder whether Holmes's mixing of cocaine with his morphia, against which I had more than once warned him, had at last affected his once brilliant brain. And his next remark, as to confute his wild ramblings I reached down the revered and well-thumbed volume of Cunningham from my shelves, only served to confirm this

sad suspicion. "If one were to describe exactly what one finds in the human body, uncaring whether or not it agrees with the books..."

Here the fragment ends.—I am, etc.,

London, W.1, Sept. 8th.

DENIS BROWNE.

Orthopaedic Treatment of Infantile Paralysis

SIR.—In these observations I particularly desire to draw attention to those developed cases of extensive muscle weakness in the lower limbs which six months after the onset of this disease show few clinical signs of recovery.

For example, a child of 6 years of age is found at the original examination to have apparently no power of movement in the left leg, and in the right leg movement of toes only. After six months of complete rest (recumbency on a satisfactory splint), competent trained nursing, and orthopaedic supervision the following condition is found: there are still no signs of recovery of voluntary power in the left leg, but in the right are found early evidences in all the muscle groups. At this stage a complete return of normal muscle function in the right leg is unlikely, while the prognosis as to any improvement in the left leg has to be most guarded. Due consideration having been given to this difficult subject of prognosis the time has arrived for anxious thought regarding the future of a patient who is obviously going to be grossly handicapped in the struggle for existence. It has become necessary to plan the life and the treatment of the individual for ten or twenty years in advance. The earlier this problem is faced in all its aspects—medical, financial, and educational—the better for everyone concerned.

It has been my privilege to supervise personally the orthopaedic treatment of cases of this description from early childhood up to adult life, and I strongly advocate that "the long view" must be taken with every patient. During this extended treatment the essential aims to be kept in view are the following. First, the prevention of any deformity, especially one of a crippling nature; secondly, the ultimate attainment of the power of walking in a manner approaching as closely as possible to normal; and, thirdly, education in a manner best suited to ensure the capacity for earning a living.

The crux of the problem is contained in the following statement. All the essentials enumerated above are obtainable for the majority of these cases of lower limb paralysis if weight bearing is deferred until it is reasonably certain that no further gain in muscle power is possible, and that no gross muscle fatigue is likely to result. The time limit for recumbency will be a variable factor in each individual case and with individual professional experience, but I have no hesitation in advocating a minimum period of two years in every case of lower limb paralysis. In severe cases, as in the example quoted above, this period may be extended to three, four, or even five years. The only standard must be the capacity of the injured limbs to support the weight of the body. No other problem in the whole course of treatment approaches this in importance, and an error of judgement in this particular may mar the whole future life.

Too early weight bearing will cause fatigue, produce muscle weakness and deterioration, and possibly precipitate a state of crippledom which no after-treatment can wholly remedy. It is a very hard struggle to convince parents and others of the necessity "to hasten slowly" before taking this vital step. They see considerable improvement in the child's condition while strict recumbency is being maintained, and constantly desire to know when the child will be allowed to stand.

This dangerous importunity must be resisted and the plan previously mapped out stubbornly adhered to. A constant propaganda explaining the evils of too early weight bearing has to be carried on. Lest my proposition should appear fantastic, I may point out that in the case of tuberculosis of the hip-joint it has been brilliantly successful. All concerned with the treatment of tuberculosis of this joint have been educated to appreciate that there is no time limit for treatment. The moment for weight bearing in this disease is left absolutely to the judgement of the surgeon. Muscle and bones, which are grossly weakened following upon an attack of infantile paralysis, are at least equally as important as

infected joints and worthy of the same careful treatment. Looking ahead and visualizing the adult life of the individual, what is the loss of these early years in childhood compared with the certainty that the maximum amount of recovery possible has been obtained. These weak lower limbs, with or without the assistance of steel splints, crutches, etc., will ultimately be required to support the weight of a body, often proportionately well developed, throughout the remainder of the patient's existence.

Recumbency on a splint of the type of the late Sir Robert Jones's abduction frame, modified to suit individual cases, is the ideal position of rest. During this extended period of rest the problem of obtaining movement without weight bearing and with gradually increasing power and range must be tackled with confidence. This is the method of treatment known as muscle re-education, with its principles of the zero position of muscle, the stress laid on the action of gravity as a factor in all muscle work, and the conception that by very gradually increasing the load a muscle has to bear it is possible to blow into flame any tiny spark of movement. Originally described by Sir Colin Mackenzie more than twenty years ago, and since then constantly advocated and demonstrated by both of us, these methods are now widely known and practised wherever the treatment of paralysis has been modernized.

An attempt has been made in this review to show the life of a sufferer from the effects of infantile paralysis in perspective. No considerations of a financial character have been allowed to interfere with what is held to be the only method of treatment which will prevent the distressing crippledom, still all too prevalent as an aftermath of this disease. A comparison with treatment of tuberculosis of the hip-joint has been instituted to show that this ideal treatment advocated is not possible of achievement. In conclusion, I wish to emphasize that at no stage in the treatment of the extensive muscle weakness caused by this disease can we say that treatment is finished. These patients must be seen at frequent regular intervals after weight bearing has been permitted, and must be carefully overhauled to prevent the development of insidious muscle maladjustments. Considering its overwhelming importance in the plan of treatment, a plea for "the long view" cannot be made too strongly.

—I am, etc.,

CHARLES MACKAY, M.D. Melb.

Malaga, Spain, Aug. 29th.

Sodium Evipan

SIR,—We have used sodium evipan with complete satisfaction in a number of cases of Arabs and Jews, and as the results merely confirm the observations of others there is no need to detail them, except perhaps to note in passing that the oral administration of morphine grain 1/4 a few minutes before the operation seems greatly to lessen the "drunken" effects experienced by some nervous subjects on emerging from evipan anaesthesia. Two cases are, however, worth noting briefly.

1. A male Arab, aged 45, believed to be slightly mentally defective, reached us in a very toxic state by reason of a tropical ulcer which had eroded the tibia shaft and the whole of the postero-lateral aspect of the left leg. As inhalation anaesthesia seemed to be contraindicated sodium evipan was chosen, since amputation was imperative. The patient died of cardiac collapse before the operation was started, although the usual precautions had been observed. It is not possible to exclude the idea that he would have died within a matter of hours even without any anaesthetic, but the case must be recorded as a death under this anaesthetic.

2. A male Arab, aged 28, arrived in a state of constant spasm due to tetanus. His symptoms were seven days old at the time of admission. He was rigid from occiput to heels, the jaw being fixed and the arms flexed at the elbows, so that the clenched hands were above his head, and both in spasm. Treatment consisted in intramuscular magnesium sulphate (5 c.cm. of a 25 per cent. solution) every five hours, 3,000 units of antitetanic serum daily (this serum is limited

in supply in Aden), morphine grain 1/4 at first twice a day, and 10 c.cm. of sodium evipan solution each evening. The continuous spasm gave place to spasm every three minutes, and thereafter the patient made an uneventful recovery. We believe sodium evipan to be of definite value in tetanus.

—We are, etc.,

Control of Prophylactic X-Ray Treatment in Breast Cancer by Serum Tests

SIR,—In your report of the proceedings of the Radiological Section at the British Medical Association Annual Meeting (*Journal*, August 11th, p. 275) I note that Dr. H. Guy Dain said that he doubted the value of repeated x-ray treatment after radical mastectomy for carcinoma of the breast. It must be admitted that prophylactic post-operative treatment by x rays has in the past been of an empirical nature. While the failures have been evident it has always been open to opponents to claim that those patients who have survived a long time would in any case have done so. Workers who believed that resistance to metastases could be increased by small doses of x rays had no means of putting their views to the test of laboratory findings. Statistics, as usual, have been quoted by upholders, and destructively criticized by opponents. The time has now come, however, when advances in biochemistry make it not only possible but incumbent upon us to take note of the constitutional effects of x-ray treatment, so that we may decide in any given case what is to be aimed at—that is to say, whether we are to use radiation in concentrated form over a strictly limited area in order to maintain a local reaction; or over a wide field, employing low intensity, to alter the metabolism of the body.

The study of x-ray effects on the blood in certain diseases can now be carried out by means of a modification of the Bendien tests. These tests have been described in detail in the *British Medical Journal* (1933, i, 407, 536) by Dr. Cronin Lowe. It was, I believe, Dr. Lowe who first suggested that the vanadic acid test might be used not only as a means of telling when a breast cancer patient was in danger of a metastatic outbreak, but also as a means of gauging the patient's response to x rays or other therapeutic measures. The precise value of the tests in differential diagnosis need not be discussed here, because we are dealing with cases in which the nature of the disease is known. In order that it should be valuable as a control for x-ray therapy it is necessary: (a) that the test should be positive in nearly all cases with active lesions, either primary or metastatic; (b) that it should become negative in a certain proportion of cases of operative removal or local disappearance under radium or x rays; and (c) that where it remains, or again becomes, positive, local or metastatic recurrence should usually take place in the course of a few months. Drs. Cronin Lowe, Harry Coke, and others who have experience of the tests state that these criteria are fulfilled: if radiologists wish to try out the tests as a therapeutic control they must assume, as a working hypothesis, that the statement is correct.

During the past six months every case of cancer of the breast which has come under my care, whether in hospital or in private practice, has been subjected to the vanadic acid test at the hands of Dr. Harry Coke. As a result of over forty blood examinations I am prepared to make certain statements with regard to the test.

1. It has been positive in all cases which showed clinical activity. Here x-ray treatment has improved the blood picture, but not made it fully normal.

2. The test has also been positive in some post-operative cases which showed no clinical evidence of disease. In some of these cases a satisfactory blood picture has been restored by x rays; in others there has been improvement only. So far none in this group has developed macroscopic metastases.

3. The favourable response is due to some generalized action, and is brought about by small repeated doses over a wide field. It is extremely easy in susceptible patients to make the blood picture worse, though if this is detected in time no harm is done, as it improves on cessation of the treatment. The lesson taught is that x-ray dosage for constitutional purposes requires individual control.

In breast cancer the control of metastases is the ultimate problem. If the vanadic acid test really gives us an indication of metastatic activity in its microscopic stages, there is a chance of doing something in time. We do not yet know if obvious secondaries can at times develop in the face of a normal blood picture, nor do we know for how long we can maintain a normal blood picture in cases where x-ray treatment has brought it back from an abnormal state. But it would seem just as rational to make repeated blood tests in the case of carcinoma mammae, and act accordingly, as it is to do Wassermann tests in the case of a patient who has been "cured" of syphilis. The vanadic acid test may help to abate the controversy between those who say "let well alone" and those who retort that one can never be sure that all is well. Unless and until the test can be proved valueless as an indication of latent secondary mischief, he would be a bold man who would refuse to take some action in the case of a patient apparently in good health but showing an unfavourable blood picture.

In conclusion, I should like to point out that the above remarks have no bearing upon the question of localized dosage in other forms of cancer, or even upon the dosage requisite for the primary growth in cancer of the breast itself when that is dealt with by radiation.—I am, etc.,

London, W.1, Aug. 26th.

F. HERNAMAN-JOHNSON.

The Swab in Diphtheria Diagnosis

SIR,—Your kind reference to my method in last week's *Journal* (p. 476) has suggested to me that it might be advantageous if I were to offer to supply to bacteriologists who have not used it some of the stain, together with notes on its application. I write to say, therefore, that I shall be delighted to do so to anyone who cares to write to me direct. I believe samples of toluidin-blue vary in their suitability for this method of staining, and it is therefore important to have a reliable brand. Your article brought out one important point which I had omitted from my letter—namely, its value for immediate diagnosis of Vincent's angina.—I am, etc.,

CONSTANT PONDER.

Sessions House, Maidstone, Sept. 10th.

SIR,—It appears that my letter on this subject has been misunderstood to some extent. I did not wish to convey the idea that the taking of swabs should be abolished; my intention was to infer that, while a swab should be taken, the greatest care should be exercised in the event of a negative report before the case is definitely classified as not being diphtheria, and that in making a diagnosis the bacteriologist's report must be considered in conjunction with the clinical aspects of the case.—I am, etc.,

Brighton, Sept. 8th.

J. C. T. SANCTUARY.

Obituary

CARL OLAF JENSEN, M.D.

Director of the Serological Laboratory, Danish Veterinary and Agricultural College

The announcement of the sudden death of Professor C. Olaf Jensen in Copenhagen on September 3rd must have awakened feelings of intense regret in the minds of thousands, and especially among medical men and veterinary surgeons.

Professor Jensen achieved world-wide fame by his researches regarding the experimental transmission of cancer, but these occupied only a small part of his active life, which was mainly devoted to the study of the contagious diseases of the domesticated animals. In a lecture delivered in Copenhagen in 1901, and more fully in a paper published in 1903, he showed that a malignant tumour occurring in mice could be readily transmitted to healthy animals of the same species by inserting a small particle of the tumour under the skin—a process he named "transplantation" to distinguish it from inoculation. The tumour in question was a carcinoma or adenocarcinoma, and the new growths which developed from the transplanted particle were found to be of the same nature as the naturally occurring tumours in mice. It was furthermore proved that by this process of transplanting or grafting the tumour could be transmitted in series through many generations, if not indefinitely. The cells of the experimentally produced tumours showed the capacity for uncontrolled multiplication which is now recognized to be the property that distinguishes the cells of malignant new growths from those of the normal body.

Jensen's success, where others had failed, was due to the fact (1) that the attempts to transmit the tumours were made with animals of the same species, and (2) that the method of transmission adopted was that of transplanting or grafting of the living tumour cells. It would scarcely be possible to exaggerate the practical importance of Jensen's great discovery. Its value lay not in what the experiments proved in regard to malignant tumours in mice, but in the fact that it pointed the new way in which researches regarding malignant tumours in animals might profitably be pursued. In fact, a large part of the new knowledge regarding malignant neoplasms since 1901 has been obtained by investigations on the lines suggested by the pioneer work of Jensen. It was he who discovered that the cancer cells of the mouse tumours possessed a remarkable viability compared with the ordinary cells of the body, and remained alive at ordinary temperatures for many days after removal of the tumour. This made it possible to transmit what may be called the seeds of Jensen's mouse tumours from Copenhagen to laboratories in other parts of the world, including those of the Imperial Cancer Research Fund in London. In this way there began a period of intense experimental study of cancer problems in which the method initiated by Jensen played a prominent part.

His other contributions to animal pathology included valuable papers on braxy (1896), diarrhoea in young calves (1891, 1892, and 1911), necrobacillosis (1897), and contagious bovine abortion (1933). All of these papers embodied results of the author's original investigations, and he was the first to prepare specific antisera for use against the first two diseases. The paper on contagious abortion was his latest contribution to veterinary literature; in it he reported the results of experiments in the use of vaccines for the prevention of contagious abortion, and drew conclusions very adverse to the method that has been extensively practised in this and other countries.

THE LATE DR. R. A. GIBBONS

The obituary notice published last week (p. 493) should have mentioned Dr. R. A. Gibbons's long and valued association with the Medical Insurance Agency. He was elected to the Committee of Management on November 21st, 1918, and thenceforward continued to attend its meetings with great regularity. A few further biographical details of Dr. Gibbons's career have been sent to us by a member of the family. His father was Commissary General David Gibbons in the English Army, and his mother was Elizabeth Frances, daughter of Captain James Ireland-Wilkinson, R.N. It was merely owing to the accident of his father being stationed in Canada for a few years, in a military capacity, that he was born there; he was brought to England while a baby in arms. His parentage was of Scottish origin, and he was brought up in Edinburgh.

On August 12th, at his home at Snainton, Yorks, the death took place of Dr. GEORGE HARDWICKE, aged 58 years, after a long and tedious illness. Dr. Hardwicke completed his medical education at the General Infirmary at Leeds, taking the diplomas of M.R.C.S. and L.R.C.P. in 1897. During the same year he won the prizes in medicine, surgery, and midwifery. After qualification he held the following appointments: house-physician, General Infirmary at Leeds; resident surgical officer, Ida Convalescent Home; senior house-physician, Leeds Public Dispensary; and assistant resident medical officer, Leeds City Fever Hospitals. In 1917 he received a commission in the R.A.M.C. and held the rank of captain, served with the 83rd Field Ambulance, 21st Division, Salonika, and was mentioned in Sir G. F. Milne's dispatches. While on active service he contracted the illness from which he eventually died. Dr. Hardwicke went to Snainton thirty years ago, and during that time played a prominent part in the life of the countryside. He was keenly interested in sport, and was a recognized authority on the Yorkshire dialect, and had addressed the Society of Yorkshiremen in London and Lincoln on this subject, in addition to writing several short stories and sketches in dialect. Several years before the outbreak of war he became interested in Red Cross work, for which cause he did a great deal, and before joining the Army had charge of Wydale Auxiliary Hospital and Wykeham Red Cross Hospital. He had been a member of the Scarborough Division of the British Medical Association since 1899. During his life in Snainton he greatly endeared himself to all who came in contact with him. His understanding and ready sympathy with those in trouble will ever be remembered, and the loss is a great one to the whole countryside.

The Services

D.G.M.S. AUSTRALIAN MILITARY FORCES

The appointment is announced of Colonel Rupert Major Downes, C.M.G., V.D., as Director-General of Medical Services to the Military Forces of the Commonwealth of Australia, in succession to Major-General George W. Barber, C.B., C.M.G., D.S.O., who retires in November, 1934, on reaching the age limit.

General Barber was born in Prestwich, Lancashire, and began life as a sailor, but later had to abandon the sea owing to defective eyesight. He studied medicine in London at the Middlesex Hospital, and obtained the M.R.C.S., L.R.C.P. diplomas in 1891. He then joined the P. & O. Line as a ship surgeon and spent some years at sea. In 1895 he settled in the goldfields at Kalgoorlie, Western Australia, where for many years he was Government Medical Officer. In 1911 he commenced private practice in Perth, where, as at Kalgoorlie, he achieved a wide reputation as a general practitioner and surgeon. The third phase of his career began in 1900 when he joined the Australian Army Medical Corps. On the outbreak of war in 1914 he was mobilized as senior medical officer of the Fremantle Garrison.

He left Australia in December, 1914; with the Second Australian General Hospital, and served in Egypt, Lemnos, and Gallipoli with the rank of major. After the evacuation of Anzac he was A.D.M.S. of the 4th Australian Division, with the rank of colonel, and served in France till the end of the war. In April, 1918, he was appointed D.D.M.S. of the Australian Corps, and gave signal service in this capacity. On returning to Australia he was appointed D.D.M.S. of Western Australia, and in 1925 he succeeded Sir Neville Howse as Director-General of the Medical Services for the Commonwealth. General Barber was awarded the Orders of the C.B., C.M.G., and D.S.O., the French Croix de Guerre, and was mentioned in dispatches eight times.

Colonel Rupert Downes also had a career unusual for a medical man. His father, Major-General M. F. Downes, C.M.G., served in the Royal Artillery in the Crimean War, and after acting as Commandant of South Australia became Secretary of Defence for Victoria and then Commandant of Victoria during the period of the South African War. Colonel Rupert Downes was born in Adelaide in 1885, and was educated at Haileybury College, Melbourne. As a resident in Ormond College he graduated M.B., B.S. Melb. in 1907. He obtained his University blues for cricket and tennis. After graduation he became surgical tutor at Ormond College, and proceeded M.D., M.S. Practising in Melbourne as a consulting surgeon, he held several surgical hospital appointments, and at the time of his appointment as D.G.M.S. he was in-patient surgeon at the Children's Hospital, Melbourne, and consulting surgeon to the Eye and Ear Hospital. Among his other appointments are those of Commissioner of the St. John Ambulance Brigade and president of that association, chairman of the Board of the Victorian Branch of the Australian Massage Association, member of the Council and vice-president of the British Medical Association (Victorian Branch), and lecturer in medical ethics. His military record dates from 1900, when, as a boy trumpeter, he enlisted in "B" Battery, Victorian Field Artillery, with which he served for eight years. In 1908 he obtained his first commission in the Australian Army Medical Corps, and was an enthusiastic medical officer during the pre-war years. Shortly after the outbreak of war he volunteered for active service, and his first command was the 3rd Light Horse Field Ambulance in 1914-15 in Egypt and Gallipoli. Before the evacuation he was appointed A.D.M.S. of the New Zealand and Australian Division at Anzac. After the evacuation he was appointed A.D.M.S. of the Anzac Mounted Division in Egypt and Palestine, and later held the appointment of D.D.M.S. of the Desert Mounted Corps in Sinai, Palestine, and Egypt. He was thus responsible for the medical services of the greatest mounted force ever assembled in modern times. Towards the end of the war he was D.D.M.S. of the A.I.F. in Egypt. He was awarded the C.M.G. and mentioned in dispatches four times. In the Commonwealth Military Forces since the war he held the appointment of D.D.M.S., Third Military District (Victoria), from 1921 to 1934. He was a member of the Committee on Reorganization of the Medical Service in 1920 and the representative of the medical profession on the Commonwealth War Book Committee. He has also held the appointment of honorary surgeon to the Governor-General.

It must be understood that in Australia, in contradistinction to the practice in Britain, there is only one medical officer in the permanent military forces in the person of the D.G.M.S. The remaining appointments are filled by citizen soldiers. This service makes a considerable demand on the time and energies of men in active medical practice, with the result that a great proportion of the administrative work is done by officers and warrant officers of the permanent forces without medical training.

43RD FIELD AMBULANCE DINNER

The committee responsible for organizing a reunion of members of the 43rd Field Ambulance, R.A.M.C., has decided to hold a dinner at the Grosvenor Hotel, Deansgate, Manchester, on Saturday, October 27th, at 6 p.m. Price of ticket, 5s. 9d.; evening dress optional. To enable the committee to assess the number who will be present, applications for tickets, with remittance, should be made before October 15th to Mr. W. C. Dickson, 76, Boswall Drive, Edinburgh.

DEATHS IN THE SERVICES

Brevet Colonel Charles Bunbury Lawson, late R.A.M.C., died in London on July 30th, aged 66. He was born at Ballinagarry, Ireland, on August 3rd, 1867, and was educated at Edinburgh, where he graduated M.B., C.M. in 1889. Entering the Army as surgeon lieutenant on January 30th, 1892, he became lieutenant-colonel on August 3rd, 1914, got a brevet as colonel on February 18th, 1915, and retired on April 10th, 1920. During his career he specialized as a radiologist. He was medical officer to H.R.H. the Duke of Connaught while commander-in-chief in the Mediterranean; pathologist and radiologist to the Royal Herbert Hospital, Woolwich, in 1903; examiner in surgery, pathology, and radiology to the Royal Army Medical College at Netley in 1903; and pathologist, radiologist, and surgical specialist at Malta from 1903 to 1908. He held the same offices at the Royal Victoria Hospital, Netley, 1908 to 1912; and also, after the war, at Colchester in 1918-20; and was radiologist and medical assessor to the Ministry of Pensions in 1923-5. He served in the South African War in 1899-1900, when he took part in the advance on Kimberley, and received the Queen's medal, with a clasp; and in the war of 1914-18, when he was mentioned in dispatches in the *London Gazette* of February 17th, 1915. He was for forty-one years a member of the British Medical Association.

Medical News

Dr. Henry MacCormac will deliver the introductory address, entitled "Our Profession," at the opening of the winter session of the Middlesex Hospital Medical School, at the Queen's Hall, Langham Place, on Monday, October 1st, at 3 p.m., after which Sir E. Farquhar Buzzard, Bt., will distribute the prizes. The annual dinner takes place the same day at 7.30 o'clock at the Savoy Hotel.

The Westminster Hospital Medical School annual dinner will be held at the Trocadero Restaurant on Saturday, September 29th. A special post-graduate course for old students has been arranged for Saturday, September 29th, and Sunday, September 30th. The inaugural address will be given by Sir John Simon in the Central Hall on Monday, October 1st, at 3.30 p.m.

The annual dinner of past and present students of King's College Hospital Medical School will be held on Saturday, September 29th, at 8 p.m., at the Connaught Rooms, with Dr. Wilfrid Attenborough in the chair. An intensive post-graduate course will be held on Saturday, September 29th, 12 to 6 p.m., and on Sunday morning, September 30th, to which members of the school and other practitioners are invited. A series of post-graduate lectures, free to all practitioners, will be delivered in the lecture theatre on Thursdays, at 9 p.m., from October 11th, 1934, to April 4th, 1935. The opening lecture will be given by Mr. Cecil Wakeley. Subsequent lectures will be announced weekly in our medical diary.

The thirteenth reunion dinner of the British Serbian Units Branch of the British Legion will be held on Thursday, September 27th, at the Lysbeth Hall, Soho Square, London, at 7.30 p.m. Lieut.-Colonel A. E. Kidd will preside, and a large party of ex-servicemen from Yugoslavia are expected to be present. Tickets may be obtained from Miss Marx (24, Melcombe Court, Dorset Square, N.W.1). All friends of Serbia are welcome.

The next extra-metropolitan dinner of the University of London Medical Graduates' Society will be held on Friday, September 28th, at 7.30 p.m., in Queen's College, Cambridge. Members should apply for tickets, enclosing the sum of 8s. 6d., to the honorary secretaries not later than September 24th, at 11, Chandos Street, Cavendish Square, W.

The annual address at the Central London Throat, Nose, and Ear Hospital (Gray's Inn Road, W.C.) will be given by Mr. Douglas Harmer on Friday, October 12th, at 4 p.m. His subject is "Treatment of Malignant Disease in the Upper Jaw."

The fifteenth Norman Kerr Memorial Lecture will be delivered before the Society for the Study of Inebriety by Sir Malcolm Delevingne, lately British Representative on the Opium Advisory Committee of the League of

Nations, on Tuesday, October 2nd, at 4 p.m., in Friends House, Euston Road, N.W. His subject is "Some International Aspects of the Problem of Drug Addiction." Each member and associate is at liberty to introduce visitors.

The London County Council announces that a three-months' course of lectures and demonstrations in connexion with instruction in hospital administration for the D.P.H. will be given at the North-Western Hospital, N.W.3, and at the Brook Hospital, S.E.18, from October 1st, on Mondays and Wednesdays at 9.30 a.m., and alternate Saturdays at a time to be arranged. These courses comply with the requirements of the revised regulations of the General Medical Council, which came into operation in 1931, and the fee for each is £3 13s. 6d. A course may, however, be taken under the previous regulations at a fee of £4 4s. Medical men desiring to take either course must pay beforehand the requisite fee to the Medical Officer of Health, London County Council, Public Health Department (Special Hospitals), County Hall, S.E.1, giving full name and address.

The following international medical post-graduate courses have been arranged for October by the Berlin Academy for Medical Post-Graduate Training, under the auspices of the Lord Mayor of Berlin, and in succession to the Society of Lecturers for Medical Post-Graduate Training in Berlin: Internal medicine, with special regard to tuberculosis, from the 1st to 13th—fee, RM. 60; course in tuberculosis in the tuberculosis hospital of Berlin, Waldhaus Charlottenburg, in Sommerfeld, from the 15th to 20th—fee, RM. 50 (accommodation and board can be obtained for RM. 2.7 per day); obstetric-gynaecological post-graduate training week, from the 15th to 20th—fee, RM. 50; course in diseases of the ear, nose, and throat, from the 1st to 13th—fee, RM. 120; course in paediatrics, from the 22nd to 27th—fee, RM. 50; surgical intrathoracic diseases, with special regard to pulmonary tuberculosis, from October 29th to November 2nd—fee, RM. 80. Individual courses in all branches of medicine with bedside and laboratory practice are held every month. The fee is RM. 50 to RM. 80 for eight lessons of two hours each, special attention being paid to practical work. Programmes and further particulars are obtainable from the Academy, Berlin, N.W.7, Robert-Koch-Platz 7 (Kaiserin Friedrich-Haus). German as well as foreign doctors can attend the courses, and foreign students obtain a reduction of 60 per cent. in fares from the German railways.

The Fellowship of Medicine and Post-Graduate Medical Association announces that lecture-demonstrations will be given at 11, Chandos Street, Cavendish Square, at 2.30 p.m. on Tuesdays as follows: "Hemiplegia" on September 18th and "Paraplegia" on September 25th. Forthcoming courses include chest diseases at the Brompton Hospital, September 24th to 29th; proctology at the Gordon Hospital during the same period; disease of children at the Queen's Hospital, October 1st to 13th; dermatology at St. John's Hospital from October 1st to 27th; and an evening series of lectures on physical medicine at the St. John Clinic and Institute of Physical Medicine during the same period. A course in medicine and surgery will be held at the Metropolitan Hospital from October 8th to 20th, and a week-end course in diseases of the heart and lungs at the Royal Chest Hospital on October 13th and 14th.

Post-graduate lectures and demonstrations will be given by members of the honorary staff of the Manchester Royal Infirmary on medical, surgical, and special subjects each week on Tuesdays and Fridays, from September 25th to December 18th. All lectures begin at 4.15 p.m. and are free. Details may be obtained from the secretary for the post-graduate lectures.

The thirty-fourth congress of the French Association of Urology will be held at the Paris Faculty of Medicine on October 8th under the presidency of Dr. Heitz-Boyer, when the subject for discussion will be orchio-epididymitis apart from syphilis and tuberculosis, introduced by Dr. Chauvin of Marseilles. Further information can be obtained from Dr. O. Pasteau, 13, Avenue de Villars, Paris, 7c.

THE LATE DR. R. A. GIBBONS

The obituary notice published last week (p. 493) should have mentioned Dr. R. A. Gibbons's long and valued association with the Medical Insurance Agency. He was elected to the Committee of Management on November 21st, 1918, and thenceforward continued to attend its meetings with great regularity. A few further biographical details of Dr. Gibbons's career have been sent to us by a member of the family: His father was Commissary General David Gibbons in the English Army, and his mother was Elizabeth Frances, daughter of Captain James Ireland-Wilkinson, R.N. It was merely owing to the accident of his father being stationed in Canada for a few years, in a military capacity, that he was born there; he was brought to England while a baby in arms. His parentage was of Scottish origin, and he was brought up in Edinburgh.

On August 12th, at his home at Snainton, Yorks, the death took place of Dr. GEORGE HARDWICKE, aged 58 years, after a long and tedious illness. Dr. Hardwicke completed his medical education at the General Infirmary at Leeds, taking the diplomas of M.R.C.S. and L.R.C.P. in 1897. During the same year he won the prizes in medicine, surgery, and midwifery. After qualification he held the following appointments: house-physician, General Infirmary at Leeds; resident surgical officer, Ida Convalescent Home; senior house-physician, Leeds Public Dispensary; and assistant resident medical officer, Leeds City Fever Hospitals. In 1917 he received a commission in the R.A.M.C. and held the rank of captain, served with the 83rd Field Ambulance, 21st Division, Salonika, and was mentioned in Sir G. F. Milne's dispatches. While on active service he contracted the illness from which he eventually died. Dr. Hardwicke went to Snainton thirty years ago, and during that time played a prominent part in the life of the countryside. He was keenly interested in sport, and was a recognized authority on the Yorkshire dialect, and had addressed the Society of Yorkshiresmen in London and Lincoln on this subject, in addition to writing several short stories and sketches in dialect. Several years before the outbreak of war he became interested in Red Cross work, for which cause he did a great deal, and before joining the Army had charge of Wydale Auxiliary Hospital and Wykeham Red Cross Hospital. He had been a member of the Scarborough Division of the British Medical Association since 1899. During his life in Snainton he greatly endeared himself to all who came in contact with him. His understanding and ready sympathy with those in trouble will ever be remembered, and the loss is a great one to the whole countryside.

The Services

D.G.M.S. AUSTRALIAN MILITARY FORCES

The appointment is announced of Colonel Rupert Major Downes, C.M.G., V.D., as Director-General of Medical Services to the Military Forces of the Commonwealth of Australia, in succession to Major-General George W. Barber, C.B., C.M.G., D.S.O., who retires in November, 1934, on reaching the age limit.

General Barber was born in Prestwich, Lancashire, and began life as a sailor, but later had to abandon the sea owing to defective eyesight. He studied medicine in London at the Middlesex Hospital, and obtained the M.R.C.S., L.R.C.P. diplomas in 1891. He then joined the P. & O. Line as a ship surgeon and spent some years at sea. In 1895 he settled in the goldfields at Kalgoorlie, Western Australia, where for many years he was Government Medical Officer. In 1911 he commenced private practice in Perth, where, as at Kalgoorlie, he achieved a wide reputation as a general practitioner and surgeon. The third phase of his career began in 1900 when he joined the Australian Army Medical Corps. On the outbreak of war in 1914 he was mobilized as senior medical officer of the Fremantle Garrison.

He left Australia in December, 1914; with the Second Australian General Hospital, and served in Egypt, Lemnos, and Gallipoli with the rank of major. After the evacuation of Anzac he was A.D.M.S. of the 4th Australian Division, with the rank of colonel, and served in France till the end of the war. In April, 1918, he was appointed D.D.M.S. of the Australian Corps, and gave signal service in this capacity. On returning to Australia he was appointed D.D.M.S. of Western Australia, and in 1925 he succeeded Sir Neville Howse as Director-General of the Medical Services for the Commonwealth. General Barber was awarded the Orders of the C.B., C.M.G., and D.S.O., the French Croix de Guerre, and was mentioned in dispatches eight times.

Colonel Rupert Downes also had a career unusual for a medical man. His father, Major-General M. F. Downes, C.M.G., served in the Royal Artillery in the Crimean War, and after acting as Commandant of South Australia became Secretary of Defence for Victoria and then Commandant of Victoria during the period of the South African War. Colonel Rupert Downes was born in Adelaide in 1885, and was educated at Haileybury College, Melbourne. As a resident in Ormond College he graduated M.B., B.S.Melb. in 1907. He obtained his University blues for cricket and tennis. After graduation he became surgical tutor at Ormond College, and proceeded M.D., M.S. Practising in Melbourne as a consulting surgeon, he held several surgical hospital appointments, and at the time of his appointment as D.G.M.S. he was in-patient surgeon at the Children's Hospital, Melbourne, and consulting surgeon to the Eye and Ear Hospital. Among his other appointments are those of Commissioner of the St. John Ambulance Brigade and president of that association, chairman of the Board of the Victorian Branch of the Australian Massage Association, member of the Council and vice-president of the British Medical Association (Victorian Branch), and lecturer in medical ethics. His military record dates from 1900, when, as a boy trumpeter, he enlisted in "B" Battery, Victorian Field Artillery, with which he served for eight years. In 1908 he obtained his first commission in the Australian Army Medical Corps, and was an enthusiastic medical officer during the pre-war years. Shortly after the outbreak of war he volunteered for active service, and his first command was the 3rd Light Horse Field Ambulance in 1914-15 in Egypt and Gallipoli. Before the evacuation he was appointed A.D.M.S. of the New Zealand and Australian Division at Anzac. After the evacuation he was appointed A.D.M.S. of the Anzac Mounted Division in Egypt and Palestine, and later held the appointment of D.D.M.S. of the Desert Mounted Corps in Sinai, Palestine, and Egypt. He was thus responsible for the medical services of the greatest mounted force ever assembled in modern times. Towards the end of the war he was D.D.M.S. of the A.I.F. in Egypt. He was awarded the C.M.G. and mentioned in dispatches four times. In the Commonwealth Military Forces since the war he held the appointment of D.D.M.S., Third Military District (Victoria), from 1921 to 1934. He was a member of the Committee on Reorganization of the Medical Service in 1920 and the representative of the medical profession on the Commonwealth War Book Committee. He has also held the appointment of honorary surgeon to the Governor-General.

It must be understood that in Australia, in contradistinction to the practice in Britain, there is only one medical officer in the permanent military forces in the person of the D.G.M.S. The remaining appointments are filled by citizen soldiers. This service makes a considerable demand on the time and energies of men in active medical practice, with the result that a great proportion of the administrative work is done by officers and warrant officers of the permanent forces without medical training.

43RD FIELD AMBULANCE DINNER

The committee responsible for organizing a reunion of members of the 43rd Field Ambulance, R.A.M.C., has decided to hold a dinner at the Grosvenor Hotel, Deansgate, Manchester, on Saturday, October 27th, at 6 p.m. Price of ticket, 5s. 9d.; evening dress optional. To enable the committee to assess the number who will be present, applications for tickets, with remittance, should be made before October 15th to Mr. W. C. Dickson, 76, Boswall Drive, Edinburgh.

DEATHS IN THE SERVICES

Brevet Colonel Charles Bunbury Lawson, late R.A.M.C., died in London on July 30th, aged 66. He was born at Ballingarry, Ireland, on August 3rd, 1867, and was educated at Edinburgh, where he graduated M.B., C.M. in 1889. Entering the Army as surgeon lieutenant on January 30th, 1892, he became lieutenant-colonel on August 3rd, 1914, got a brevet as colonel on February 18th, 1915, and retired on April 10th, 1920. During his career he specialized as a radiologist. He was medical officer to H.R.H. the Duke of Connaught while commander-in-chief in the Mediterranean; pathologist and radiologist to the Royal Herbert Hospital, Woolwich, in 1903; examiner in surgery, pathology, and radiology to the Royal Army Medical College at Netley in 1903; and pathologist, radiologist, and surgical specialist at Malta from 1903 to 1908. He held the same offices at the Royal Victoria Hospital, Netley, 1908 to 1912; and also, after the war, at Colchester in 1918-20; and was radiologist and medical assessor to the Ministry of Pensions in 1923-5. He served in the South African War in 1899-1900, when he took part in the advance on Kimberley, and received the Queen's medal, with a clasp; and in the war of 1914-18, when he was mentioned in dispatches in the *London Gazette* of February 17th, 1915. He was for forty-one years a member of the British Medical Association.

Medical News

Dr. Henry MacCormac will deliver the introductory address, entitled "Our Profession," at the opening of the winter session of the Middlesex Hospital Medical School, at the Queen's Hall, Langham Place, on Monday, October 1st, at 3 p.m., after which Sir E. Farquhar Buzzard, Bt., will distribute the prizes. The annual dinner takes place the same day at 7.30 o'clock at the Savoy Hotel.

The Westminster Hospital Medical School annual dinner will be held at the Trocadero Restaurant on Saturday, September 29th. A special post-graduate course for old students has been arranged for Saturday, September 29th, and Sunday, September 30th. The inaugural address will be given by Sir John Simon in the Central Hall on Monday, October 1st, at 3.30 p.m.

The annual dinner of past and present students of King's College Hospital Medical School will be held on Saturday, September 29th, at 8 p.m., at the Connaught Rooms, with Dr. Wilfrid Attenborough in the chair. An intensive post-graduate course will be held on Saturday, September 29th, 12 to 6 p.m., and on Sunday morning, September 30th, to which members of the school and other practitioners are invited. A series of post-graduate lectures, free to all practitioners, will be delivered in the lecture theatre on Thursdays, at 9 p.m., from October 11th, 1934, to April 4th, 1935. The opening lecture will be given by Mr. Cecil Wakeley. Subsequent lectures will be announced weekly in our medical diary.

The thirteenth reunion dinner of the British Serbian Units Branch of the British Legion will be held on Thursday, September 27th, at the Lysbeth Hall, Soho Square, London, at 7.30 p.m. Lieut.-Colonel A. E. Kidd will preside, and a large party of ex-servicemen from Yugoslavia are expected to be present. Tickets may be obtained from Miss Marx (24, Melcombe Court, Dorset Square, N.W.1). All friends of Serbia are welcome.

The next extra-metropolitan dinner of the University of London Medical Graduates' Society will be held on Friday, September 28th, at 7.30 p.m., in Queen's College, Cambridge. Members should apply for tickets, enclosing the sum of 8s. 6d., to the honorary secretaries not later than September 24th, at 11, Chandos Street, Cavendish Square, W.

The annual address at the Central London Throat, Nose, and Ear Hospital (Gray's Inn Road, W.C.) will be given by Mr. Douglas Harmer on Friday, October 12th, at 4 p.m. His subject is "Treatment of Malignant Disease in the Upper Jaw."

The fifteenth Norman Kerr Memorial Lecture will be delivered before the Society for the Study of Inebriety by Sir Malcolm Delevingne, lately British Representative on the Opium Advisory Committee of the League of

Nations, on Tuesday, October 2nd, at 4 p.m., in Friends House, Euston Road, N.W. His subject is "Some International Aspects of the Problem of Drug Addiction." Each member and associate is at liberty to introduce visitors.

The London County Council announces that a three-months' course of lectures and demonstrations in connexion with instruction in hospital administration for the D.P.H. will be given at the North-Western Hospital, N.W.3, and at the Brook Hospital, S.E.18, from October 1st, on Mondays and Wednesdays at 9.30 a.m., and alternate Saturdays at a time to be arranged. These courses comply with the requirements of the revised regulations of the General Medical Council, which came into operation in 1931, and the fee for each is £3 13s. 6d. A course may, however, be taken under the previous regulations at a fee of £4 4s. Medical men desiring to take either course must pay beforehand the requisite fee to the Medical Officer of Health, London County Council, Public Health Department (Special Hospitals), County Hall, S.E.1, giving full name and address.

The following international medical post-graduate courses have been arranged for October by the Berlin Academy for Medical Post-Graduate Training, under the auspices of the Lord Mayor of Berlin, and in succession to the Society of Lecturers for Medical Post-Graduate Training in Berlin: Internal medicine, with special regard to tuberculosis, from the 1st to 13th—fee, RM. 60; course in tuberculosis in the tuberculosis hospital of Berlin, Waldhaus Charlottenburg, in Sommerfeld, from the 15th to 20th—fee, RM. 50 (accommodation and board can be obtained for RM. 2.7 per day); obstetric-gynaecological post-graduate training week, from the 15th to 20th—fee, RM. 50; course in diseases of the ear, nose, and throat, from the 1st to 13th—fee, RM. 120; course in paediatrics, from the 22nd to 27th—fee, RM. 50; surgical intrathoracic diseases, with special regard to pulmonary tuberculosis, from October 29th to November 2nd—fee, RM. 80. Individual courses in all branches of medicine with bedside and laboratory practice are held every month. The fee is RM. 50 to RM. 80 for eight lessons of two hours each, special attention being paid to practical work. Programmes and further particulars are obtainable from the Academy, Berlin, N.W.7, Robert-Koch-Platz 7 (Kaiserin Friedrich-Haus). German as well as foreign doctors can attend the courses, and foreign students obtain a reduction of 60 per cent. in fares from the German railways.

The Fellowship of Medicine and Post-Graduate Medical Association announces that lecture-demonstrations will be given at 11, Chandos Street, Cavendish Square, at 2.30 p.m. on Tuesdays as follows: "Hemiplegia" on September 18th and "Paraplegia" on September 25th. A course in medicine and surgery will be held at the Metropolitan Hospital from October 8th to 20th, and a week-end course in diseases of the heart and lungs at the Royal Chest Hospital on October 13th and 14th.

Post-graduate lectures and demonstrations will be given by members of the honorary staff of the Manchester Royal Infirmary on medical, surgical, and special subjects each week on Tuesdays and Fridays, from September 25th to December 18th. All lectures begin at 4.15 p.m. and are free. Details may be obtained from the secretary for the post-graduate lectures.

The thirty-fourth congress of the French Association of Urology will be held at the Paris Faculty of Medicine on October 8th under the presidency of Dr. Heitz-Boyer, when the subject for discussion will be orchitis-epididymitis apart from syphilis and tuberculosis, introduced by Dr. Chauvin of Marseilles. Further information can be obtained from Dr. O. Pasteau, 13, Avenue de Villars, Paris, 7e.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and **LETTERS** forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring **REPRINTS** of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to **ADVERTISEMENTS**, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The **TELEPHONE NUMBER** of the British Medical Association and the *British Medical Journal* is **EUSTON 2111** (internal exchange, four lines).

The **TELEGRAPHIC ADDRESSES** are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aithology
Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER
Westcent, London.

M.L. *a Westcent, London.*

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshuegh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Cholecystectomy and Recurrent Duodenal Ulceration

Dr. G. BRENNER SCOTT (London, S.W.16) writes: I have lately been a victim of the latest fashionable complaint—namely, cholecystitis with gall-stones. This necessitated the removal of my gall-bladder. Picturing in my mind the fact that now, instead of intermittent gushes of bile, I have a persistent seepage of bile bathing my duodenum, leads me to the rather alarming suggestion that cholecystectomy of a normal gall-bladder might be the best treatment for recurrent duodenal ulceration with its attendant and dangerous haemorrhages. May I ask your readers: (1) Do you know of any cases of duodenal ulceration following a cholecystectomy? If so, this would be fatal to my suggestion? (2) Do you know of any cases of duodenal ulceration associated with cholecystitis and cured after cholecystectomy had been performed? If so, may after cholecystectomy as a cure for recurrent duodenal ulcer be a feasible one?

After-effects of Continued Doses of Adrenaline

"L. H." asks: Can any of your readers who have observed the results of repeated injections of therapeutic doses of adrenaline over long periods, in cases of asthma and other conditions, state whether any permanent effects on the conditions, state whether any permanent effects on the health—for example, due to rise of blood pressure or any other condition—are produced? It is known that rabbits are liable to develop degenerative changes in the aorta as the result of repeated intravenous injections of adrenaline, but these animals are also prone to arterial changes from many other experimental procedures.

"Nail-biting"

Dr. RICHARD EAGER (The Mental Hospital, Exminster) writes: With due respect to the psychological aspect of this vice and the old idea that it was an indication of "bad temper," I must heartily support the advice given by Major H. Williamson of Dorchester *Journal*, August 18th as to the suggested treatment of this condition. I have for long been convinced that the intolerable irritation caused by too long nails, split nails, or "hang-nails" starts the habit of biting or tearing as the only form of relief in certain children. A pair of pocket scissors or even a file (but preferably both) which can be carried about easily will, I am sure, do much to stop the formation of this habit if appropriate instructions be given to children in whom nail-biting has commenced. It is at all events more rational than the old-fashioned application of bitter aloes and the threats of punishment previously used.

LETTERS, NOTES, ETC.

Transport of Invalids by Air

Dr. A. LANDALE CLARK (London, W.1) writes: I was recently faced with the problem of transporting a patient, aged 20 years, from London to Zurich. The patient was in a very weak condition, having had one thigh amputated for extensive osteomyelitis. It was decided that the only way in which the journey could be accomplished was by air. In co-operation with their parents I approached Imperial Airways regarding the journey. It was finally decided to reserve the forward cabin in one of their newest type of four-engined aircraft. This cabin ordinarily accommodates ten passengers. By removing the backs of four seats it was possible to erect a wooden bed, complete with special mattress. The bed was six feet long and about three feet wide, and was fitted in such a position that the patient, in a reclining attitude, had a perfect view through the windows. In addition to the patient, there were in the cabin his mother, a male nurse, and myself, and we could with comfort have had two other passengers as well. The journey started at 7 a.m., from a nursing home in the West End of London, by motor ambulance to Croydon, where the patient was lifted direct from the ambulance bed to that in the aeroplane, it being perfectly easy to run the ambulance alongside. The actual air journey started at 8.5 a.m. and we reached Zurich at 2.15 p.m., having had half an hour's stop at Paris and a quarter of an hour at Basle. The weather was, on the whole, good. At Zurich an ambulance was waiting, and again it was possible to bring it alongside the aeroplane. The patient was in bed in the clinic there at 3.15 p.m. precisely. The whole journey did not cause any unpleasant symptoms whatsoever, the only drug administered during the whole period of transit being 1/4 grain of morphine, given half an hour before arrival at Zurich. The patient ate quite a good lunch on-board, and his temperature that evening was only one degree higher than on several previous evenings in London. The next day the temperature was practically normal, and there were neither signs nor symptoms to show that he had been subjected to any undue strain or fatigue. The total expense of the journey was, I understand, between £70 and £80. Its ease and comfort were mainly due to the interest and trouble taken by members of the staff of Imperial Airways, in particular the Special Charter Department. I was shown a smaller machine, fitted nevertheless with three engines, which contained a full-length bed, besides accommodation for two other people; it can be hired as an aerial ambulance at the rate of 1s. 6d. a mile. I hope that this letter may be of service to some of my colleagues who may be faced with a similar problem.

Transport of Invalids by Railway

Dr. W. THOMSON WESTWOOD (Stretford, Manchester) writes: Dr. Maurice Campbell's experience (September 8th, p. 498) has been more fortunate than mine. I had recently occasion to have a patient moved from Manchester to Glasgow, where she was to undergo an operation immediately on arrival on account of acute cholecystitis. In spite of making every inquiry the railway company were only able to suggest taking two first-class tickets so that the invalid could ensure having one side of the compartment to herself, and as the train was expected to be busy they were unable to reserve a compartment. I should be glad to learn for future reference how these invalid coaches Dr. Campbell mentions are obtained.

Rectal Prolapse Complicated by Procidencia

Dr. D. J. CANNON (Kildare) wishes to correct a sentence in his letter under this title which appeared last week (p. 488). In paragraph 5 the fourth sentence should run: "In the female, then, if the lateral supports of the rectum are loose, complete prolapse of that organ will not occur provided the anal sphincter is intact. A high rectocele may occur instead."

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 40, 41, 42, 43, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 168.

ACUTE OSTEOMYELITIS*

BY

JOHN FRASER, M.D., CH.M., F.R.C.S.ED.

HONORARY SURGEON TO THE KING IN SCOTLAND; REGIUS PROFESSOR OF CLINICAL SURGERY,
UNIVERSITY OF EDINBURGH

I confess I have found it difficult to decide as to the best method of introducing the discussion of acute osteomyelitis. If I called it an "old friend" I would not be exaggerating, for certainly there is nothing of the parvenu about it, and yet its very familiarity is the subject of disconcerting thoughts, for we must confess that there are many problems relating to this condition which are still unsolved. We may therefore regard this choice of subject as suitable and appropriate.

I feel that it would not serve any purpose to present an outline of the subject on the basis of aetiology, pathology, etc.—these are already fully accepted and established—and I therefore prefer to treat the subject from what I might call a personal point of view, and to recall in what I am afraid may be a haphazard fashion certain of the more problematical, and therefore more interesting features of the disease. I do so in the hope that the discussion (which is, after all, the most fruitful source of enlightenment in a meeting of this kind) may throw some light upon points which to me are brimful of difficulty. Perhaps it is well that I should indicate that what I have to say applies to the acute staphylococcal infection of growing bone.

Incidence of Staphylococcal Osteomyelitis

In recent years it has been said that staphylococcal osteomyelitis is a disappearing disease—a statement with which most of us are in agreement. A statistical survey by Cecil Wakeley, based upon the analysis of hospital cases recorded in the decades 1900-10 and 1920-30, appears to bear out the truth of this statement, and it is held that the lessened incidence is explained by improvement in the general health conditions of the people, and by beneficial changes in the housing and sanitary arrangements. It has been our experience that, while this appreciation is in general correct, there has been, during the past year, a curious increase in the occurrence of the disease. This is borne out by a presentation of the numbers of osteomyelitis cases admitted year by year to one surgical charge in the Edinburgh Royal Infirmary. Over the decade May, 1924, to May, 1934, the figures are as follows:

3, 4, 2, 3, 3, 4, 5, 7, 5, 12 (48 cases).

I agree that it may be merely a coincidence, but I suspect that it may have a more stable explanation. Are the more susceptible individuals of the population entering on a phase of lessened immunity, or is the increase of staphylococcal infection a single example of a state of increased, and it may be increasing, coccal infection? I understand there has been, for example, in the autumn and early

winter a definite increase in the incidence of streptococcal infections, particularly of the haemolytic type, ascribable, in the opinion of some, to the unusually dry character of last summer. I wonder if the increase of staphylococcal incidence which we have experienced is attributable to the same influence.

Pathology

The conception of the pathology which is universally accepted is an infection of the marrow area of the bone metaphysis conveyed by the blood stream. No valid reason has ever been advanced in dispute of this view, and all experimental evidence supports its reasoning, but there is one aspect of the pathology which is not so frequently alluded to, and yet I believe that it may hold features of great significance. The haemic theory of staphylococcal osteomyelitis infection adumbrates of necessity a pre-existing staphylococcal septicaemia. I agree that the general infection may be difficult to demonstrate; I appreciate that attempts to exhibit the existence of the organism by blood culture are in the majority of cases without result; but none the less a haemic infection of a bone presupposes that staphylococcal organisms are already circulating in the blood stream, and that their localization in the bone is but a local manifestation of the general disturbance.

To the surgeon the local infection has been the important item in the clinical picture—it is upon this that he has concentrated his ingenuity and his skill; but is it right that we should regard the local focus as a most deplorable and regrettable manifestation? There is such a thing as a fixation abscess; when it appears it is regarded as a providential occurrence, for it is Nature's method of producing a defensive area from which the factors of immunity are organized and developed. From what I have seen of acute osteomyelitis the impression is growing that the focus in the bone, while it creates a difficult and regrettable situation so far as local infection and suppuration are concerned, has certain aspects which can only be regarded as defensive in their action and salutary in their effects. It is obvious that if this conception is accepted the decision will logically follow that we must reorient our attitude towards the treatment and, in fact, towards the clinical progress of the disease.

The degree of severity of the general disturbance in cases of acute osteomyelitis shows considerable variation. In a certain percentage of cases the general infection is so acute that the individual is overwhelmed in the early stages of the disease with the signs and symptoms of an intense general infection, and, as a rule, succumbs before the local evidences are manifest or confirmed. In others the general disturbance is less intense, while the picture is that of a pronounced local inflammatory reaction which quickly passes on to suppuration. If we express this

* Read in opening a discussion in the Section of Paediatrics at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

variation in terms of pathology we may argue, that in the first instance the intensity of the general infection has been in large measure dependent upon a deficient local reaction, while in the second instance the antibacterial influences released from the local focus have been efficient in counteracting the more general sepsis. If I may put the matter in a more personal way, I feel infinitely less anxious about the future of the osteomyelitis case when there is a pronounced local bone focus with early suppuration than I am when the local reaction is indefinite and suppuration absent or delayed.

Localization of the Infection

I wonder how many of us have asked ourselves why it should be that the infection of acute osteomyelitis is localized with such a remarkable degree of constancy to the metaphyseal areas of long bones? When the question is raised we are told that the localizing influences are a profuse but rather stagnant blood supply, the tissue activities of rapid growth, and the possibilities of trauma. I do not know that there is much to support any of these arguments, and in regard to the last the bulk of clinical and experimental evidence appears to negative its importance.

I venture to suggest another possible reason. The marrow of all bones, and of long bones in particular, contains a large amount of reticulo-endothelial tissue. During the period of growth, and more especially in those years when the epiphyses are being ossified and the epiphyseal plates are putting forth their greatest effort, there is an immense concentration of reticulo-endothelial cells in the metaphyseal area, where, under the demands of health, they are concerned with various phagocytic functions and the requirements of calcium metabolism. Now there is a growing volume of evidence that in the presence of general body infection the reticulo-endothelial arrangements form one of the most important defensive mechanisms of the body. We find indications of its response in septicaemia, and there are those who believe that when local suppuration appears in relation to the general infection its localization in joints or in the pleurae is an evidence of the reactive activities of reticulo-endothelial tissues.

I know that the argument is difficult to prove, but for myself I have a suspicion that in acute osteomyelitis the bone disturbance is but a local evidence of a general infection, and that the reason why the local infection is so constantly localized to the metaphysis is conceivably because we there encounter a concentration of reticulo-endothelial tissue, and that the local suppuration which results from the defensive activities of the area is in some measure protective against the general disturbance. I anticipate that this thesis will give rise to criticism, and I hope it may stimulate discussion. If space and time allowed, I would elaborate the argument to a fuller degree, but for the present it is sufficient to say that as time goes on I feel that there may be a considerable measure of truth in the theory.

Operative Treatment

It is obvious that, if one believes what I have attempted to define, one's plans of treatment must be considerably influenced by one's views, and so it has been with me. I confess that I am conservative in the matter of operation, and by that I mean that I am an advocate of what has come to be known as the Starr technique in a form which is perhaps even less extensive than that recommended by the one whose name is associated with the method. I confess I am disappointed with the results of the gutter operation, and I regard any attempt at diaphysectomy as utterly wrong in principle and ideal.

Let me describe the procedure as it is actually practised. When the diagnosis is established the infected area is exposed through a suitable incision, and, if the situation permits it, a tourniquet is used. Having exposed the affected metaphysis, the periosteum is separated, and any pus which lies in the subperiosteal area is mopped away. By means of a drill one-eighth of an inch in diameter the cortex of the metaphysis is perforated in a number of places, beginning at a point central to the epiphyseal cartilage and extending along the shaft until healthy marrow is reached. In order to lessen the risk of infecting healthy marrow, a series of drills should be available, and each should be sterilized before each successive use. The ideal is to render the cortex as porous as possible without inflicting undue disturbance upon the parts, and to attain the ideal it may be necessary to drill the cortex at intervals of a quarter of an inch over the entire area related to the infection. Through the puncture points pus and blood exude as the tension of the underlying infection is released.

The wound in the periosteum and the soft tissues is left entirely open, the part being lightly packed with sterile gauze soaked in a solution of liquid paraffin, acraflavine, and potassium citrate.* Each of these substances is understood to fulfil a special purpose—the citrate keeps the discharge in solution and so prevents the bone punctures from becoming blocked, the flavine is of course an antiseptic, which lessens the likelihood of infection spreading into the soft tissues, while the liquid paraffin facilitates subsequent removal of the gauze. Over the packing a copious gauze and wool dressing is applied, and complete immobilization is thereafter secured by encasing the limb in plaster so as to include the related joints above and below the site of the lesion.

The original dressing is kept in place for a fortnight, at the end of which time it becomes uncomfortable, and so it is our practice to remove it under light anaesthesia, to examine the wound, remove any obvious sepsis, and pack the wound afresh. A new plaster casing is applied, and in this instance it may remain *in situ* for a period of a month or six weeks. At the end of that time the wound is again examined, any sequestration which may have occurred is removed, and an attempt is made to close a section of the wound by secondary suture.

Treatment of General Condition

In a favourable case the temperature begins to fall about forty-eight hours after the operation. If on the third day it does not show signs of improvement an antistaphylococcal immuno-blood-transfusion is given, the donor having been prepared by a vaccine injection estimated on a basis of 500 million to 750 million organisms. It is my experience that an ordinary blood transfusion is of virtually no value in correcting the general sepsis, although in late cases when anaemia exists it may be of value. We have given sera what we regard as a very fair trial, using a staphylococcal serum of a polyvalent type, but we have never been satisfied that this had a beneficial effect upon the disease, and, when put to what must be regarded as the acid test—its employment in the most severe cases—it had no appreciable influence upon the progress of the disease. In so far, therefore, as the treatment of the general condition is concerned we rely upon such principles as an abundant supply of fluid, a high vitamin intake in the form of orange juice, and the use of immuno-transfusion in a certain number of cases.

Acute staphylococcal osteomyelitis must always be a serious disease, because it implies a general blood infection and the development of local sepsis in a tissue which

* The solution is acraflavine emulsion 1 in 1,000 with potassium citrate 2 per cent.

for many reasons is intolerant of such disturbance, but we have found that, if we employ a local interference which ensures relief of tension without unduly disturbing the local reaction, the results are often surprisingly good. I have therefore gone upon the principle of regarding acute osteomyelitis as a local infection which is a reaction to a septicaemia. I have viewed the local error as having a certain potential value by increasing resistance to the general infection, and on this assumption we have been satisfied with an operative procedure which ensures relief of tension and as free drainage as is possible without unduly disturbing the local tissue reactions.

Other Operative Procedures

I have abandoned the gutter operation because it did not appear to afford any more efficient drainage than that provided by the method of multiple punctures, while the trauma necessitated by the operation lessened the degree of reaction and encouraged sequestrum formation. In the same way any attempt at curetting the infected marrow encourages an embolic spread of the disease and removes the tissue segments upon which an efficient reaction depends. It has been suggested that, instead of gutting the bone, more efficient drainage might be obtained by removing $3/4$ in. of the bone circumference.

As a matter of fact this was attempted in one case, but the result was a sequestration of the remaining segment, with a state of affairs which amounted to an extensive pathological fracture.

The suggestion which has been mooted and in some cases practised, that a metaphysectomy or partial diaphysectomy should be carried out, is to my mind a wrong procedure, and the high mortality which is associated with the operation is probably due to the fact that by this means we remove the actual segment of tissue upon which the patient's resistance to the general infection may well depend. This procedure, if considered at all, should be restricted to late cases in which the entire diaphysis has become necrotic and is lying in a large subperiosteal abscess. In this event the dead shaft is already detached at each metaphyseal extremity, and the operation amounts to nothing more or less than a sequestrectomy.

Results of Operation

I conclude this somewhat disjointed discussion of the disease with a summary of the operation results. In a total of fifty-six cases observed over the last twelve years there have been thirteen deaths, a mortality of 23.2 per cent. In those who succumbed, death was due to a progressive septicaemia which ultimately passed into a pyaemia with secondary abscesses in such varied situations as voluntary muscle and subcutaneous tissue, the heart muscle, the lungs, and the brain.

S. Bueno (*Thèse de Paris*, 1934, No. 606) states that two bodies were responsible for the prophylaxis of malaria in Cuba—the State, which supervises the towns and suburbs, and the sugar companies, which are concerned with the regions in which the sugar cane is cultivated. The areas occupied by small proprietors have hardly any prophylaxis. The campaign undertaken in the towns has caused a complete disappearance of yellow fever and the almost complete eradication of malaria, especially in Havana. Considerable improvement has taken place in the country districts as the result of the measures undertaken by the American sugar companies. The apparent increase in the incidence of malaria during the season in which the sugar is produced is due to the movements of the workmen, a large proportion of whom are infected. The selection of workmen therefore appears to be desirable, only those being taken on who are free from malaria.

FUNGUS INFECTION OF THE FEET: PROPHYLAXIS AND TREATMENT*

BY

A. M. H. GRAY, C.B.E., M.D., F.R.C.P.

PHYSICIAN IN CHARGE OF SKIN DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL

Fungus infection of the feet has loomed large in the practice of dermatologists during the last twenty years or so, and in no subject in this branch of medicine has investigation been more insistently pursued and more fruitful results obtained. At the same time there are many lines of investigation which remain to be followed, and, until certain further problems are solved, many difficulties as to prophylaxis and treatment will continue.

It is not necessary for me to enter into a description of the fungi which attack the skin of the feet: suffice it to say that a considerable number of different fungi of the hyphomycetes group have been found present in these cases, and also that yeast-like organisms, generally classed under the name "*monilia*," including the organism of thrush *Monilia albicans*, have also been incriminated. Inflammations of the skin by fungi can take place in two ways: first, by the growth of the fungus in the horny layer and on the horny appendages (the hair and nails), the fungus having been implanted from without on the affected area; or secondly, by transmission of the fungus or its toxins from a local site of infection by way of the blood stream to a distant site. In this latter case some sensitization of the epidermal cells appears to be a necessary preliminary to the production of the inflammatory reactions. Reactions of this type are spoken of as "dermatophytids."

Clinical Types

Clinically, fungus disease of the feet may occur in several forms. For the sake of convenience they may be divided into three types, though some dermatologists prefer a more elaborate classification: C. J. White (*Arch. Derm. and Syph.*, April, 1927, xv, 387), for example, describes eleven types.

The types most commonly seen are: (1) the intertriginous, (2) the vesicular, and (3) the hyperkeratotic. It may be noted, however, that various combinations of these types may occur.

Intertriginous Type.—This is by far the most common, and is found between the toes, often only in the fourth interdigital space, and nearly always bilaterally. In more advanced cases other interdigital spaces are involved, as is also the fold beneath the toes. In the mildest cases perhaps only slight scaling is visible in the fourth interdigital spaces; in more chronic cases the skin of the sides of the toes becomes much thickened, appearing as a dirty white layer, owing to a great thickening of the horny layer. This thickening may occasionally become much more marked at one spot, and a so-called "soft corn" may develop. Generally the skin in the web between the toes cracks, and this crack may extend beneath the toes. In the more active cases an eczematous eruption, of either a dry or a moist character, may spread over the dorsum of the toes and anterior part of the foot, and on to the anterior part of the sole. In the most acute cases the lesions may be vesicular or bullous from the start; in fact, Whitfield states that most cases commence in this way, though on this point I am not in entire agreement with him. In this type of case secondary pyogenic infection is liable to occur, and lymphangitis may be an occasional complication. In the intertriginous

* Read in opening a discussion in the Section of Dermatology, at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

cases there is frequently involvement of the toe-nails; this is not always obvious clinically, though in many cases thickening, opacity, and brittleness of the nails may be present, but the fungus can often be found in nails which show little variation from the normal.

Vesicular Type.—In its most typical form this variety is seen as a collection of deep-seated vesicles, from pinhead to a lentil in size, usually occurring in fairly circumscribed groups on the soles of the feet, most commonly on the instep or ball of the foot. There is usually some diffuse redness surrounding the vesicles, and the patch may be sharply circumscribed and may spread by peripheral extension, or the patch may be less well defined. The vesicles vary from quite a few up to a large number. They usually appear slowly, but sometimes the whole skin of both soles may become covered with vesicles in a few hours. Although in some cases fungus can readily be demonstrated in the scales, in others repeated examinations fail to reveal its presence, and the same applies to similar lesions on the hands. It has been shown without much doubt that some of the cases belong to the group of dermatophytids, and are not direct infections. Many cases which in the old days were called cheiropompholyx or dyshidrosis are now known to be fungus infections. It is not possible here to enter into a discussion on the differential diagnosis of other vesicular and pustular eruptions of the feet.

Hyperkeratotic Type.—This form also occurs on the soles as a chronic eczematous condition, associated with much thickening of the horny layer, which is imperfectly formed and therefore liable to fissuring and exfoliation. It is most marked over points of pressure—the ball of the foot and heel. Luckily it is not such a common type as the two preceding ones.

This is a very cursory survey of the great variations which may be seen in fungus infections of the feet, but it will be noted that they are all types of an eczematous reaction, and although some of them are sufficiently typical to enable a clinical diagnosis to be made readily, others require a careful hunt for fungus before a definite diagnosis can be arrived at.

Treatment

I will now turn to consider the main subject of this paper, prophylaxis and treatment, and as the former depends to a great extent on the eradication of the disease from the infected persons I will first deal with the latter.

In order to treat the disease we must realize as completely as possible the conditions with which we are dealing. In the vast majority of cases the fungus lives entirely in the horny layer of the skin and the nails (the hairs do not require consideration in this connexion). It is true that, as I mentioned above, fungus may get into the blood stream and be conveyed to distant sites, but in these cases, for various reasons I need not discuss now, the fungus does not develop at these distant sites, and if the local supply is stopped the distant effect ceases. When fungus attacks thin skin—such as, for example, the thighs, as in *tinea cruris* (dhotie itch)—the fungus can be killed off in the horny layer with comparative ease by the use of appropriate fungicides, and can be killed off permanently. Recurrence, apart from reinfection, is rare when smooth, thin skin is involved.

It is the experience of everyone, however, that fungus affection of the feet is often difficult to cure and is prone to recur. The difficulty of cure is largely due to the great tendency that the fungus has to produce marked hyperkeratosis, which prevents the active agents from reaching it. Further, it is only in very severe cases that it is possible to prevent the patient walking about; sweating, pressure, and movement cause the disturbance of any applications in use, and also militate against the

resolution of inflammatory products. The tendency to reinfection, in my opinion, is due to the frequent involvement of the nails. It is still an open question whether it is possible to cure infected nails, except by their removal, and it would be very difficult to persuade a patient to undergo this form of treatment for what appears to him an extremely trivial condition, one which he may never even have noticed himself.

Application of Antiseptics

The difficulties which have arisen in clearing up some cases have caused dermatologists to try a very large number of different antiseptics in the treatment of these infections, but I think it is more important to lay stress on the method of applying a few known antiseptics, rather than to ring the changes on a number of different substances. My personal experience has been confined to the use of relatively few antiseptics, and I propose to confine myself to these, rather than give a list of the various remedies recommended by different observers. One must first note that one is dealing with an eczematous condition, and where the inflammation is very acute strong antiseptics and greasy preparations are not well tolerated. This applies equally to eczematous conditions caused by other micro-organisms.

In the acute bullous and vesicular types I have found the most satisfactory results are obtained by baths of 1 in 4,000 potassium permanganate and moist dressings of the same solution. It is well to prick the larger blebs before treating in this way; it is important to keep such patients off their feet, and the permanganate dressings are applied in the same way as lead lotion is applied to acute eczematous conditions—namely, without oil-silk—the lotion being applied frequently, say every hour or half-hour, and free evaporation being permitted. When the acute phase has quieted down the baths should be continued night and morning, but linimentum calaminae, with 2 per cent. ichthylol added, may be substituted for the permanganate dressings. This is applied on lint, each toe being tied up separately, and the dressings changed only twice daily. When the redness has subsided and a dry scaly condition remains then Whitfield's ointment—which is made up as follows: ac. salicyl. grains 15; ac. benzoic., grains 25; paraff. moll. 32; ol. lavand. m4; coco-nut oil ad 31 (in summer white wax may be substituted for the soft paraffin)—should be cautiously applied. It is rubbed in gently once daily, and the permanganate baths continued once daily. If any irritation is produced a return to the ichthylol should be made, and after an interval Whitfield's ointment should be tried again and continued until all scaling has ceased.

This treatment should suffice to cure a case, provided the nails are not affected. In all acute cases the horny layer exfoliates, so the difficulty of penetration of the antiseptic does not arise. Two objections have been raised to reliance on Whitfield's ointment in the treatment of fungus affections of the feet; the first is that it is not a sufficiently good fungicide. This, I think, is disproved by those who have had much experience of it clinically, but it has also been found experimentally by Gould and Carter (*Archives of Dermatology and Syphilology*, August, 1930, p. 325, and February, 1932, p. 348) to be strongly fungistatic for three of the common fungi found on the feet. The second objection is to the use of an ointment. In the chronic cases localized to the interdigital spaces there may be some force in the argument, though from clinical experience I do not think there is much in it, but for diffuse subsiding eczematoid ringworms of the feet I am convinced that an ointment is superior to any lotion, as the latter produces uncomfortable cracking of the skin, which may delay recovery, and I doubt if penetration is so good. For dry eczematous cases affecting the feet the

treatment is the same as above, but the first stage—namely, permanganate dressings—can usually be omitted. When there is much diffuse hyperkeratosis of the soles associated with a good deal of underlying inflammation again the same line of treatment is adopted, but at a suitable stage small doses of x rays (one-quarter to one-third B given weekly for three or four doses) can be added. In some cases the use of salicylic plaster is indicated.

Localized Infections

I have referred above chiefly to the more diffuse types of eruption affecting extensive areas of the feet. We will now consider the more localized types. For superficial intertriginous cases, those with only slight scaling limited to the interdigital spaces and the groove beneath the toes, Whitfield's ointment again appears to me quite a suitable remedy. Here, however, it is well to continue the treatment for some months, even though no trace of the disease is visible. I usually also order a daily foot-bath of permanganate. Whitfield's ointment, owing to the salicylic acid which it contains, and to the keratolytic properties of which it partly owes its efficacy, tends to keep up the sodden appearance of the skin. I have therefore been in the habit of ordering a bland powder, usually one part of boric acid to seven parts of talc, and have told the patient to use this alternately with the ointment—usually alternate fortnights—but this depends rather on the condition when first seen. The treatment must be carried on for two to three months after the disappearance of all scaling. When there is much horny thickening it is first necessary to deal with this. I have found daily painting with salicylic acid spirit (1 drachm to 1 ounce), followed by friction with lint, or even pumice stone, effective.

Each day before the next application the foot is soaked in permanganate and as much of the thickened horny layer as possible is rubbed or scraped away. Sabouraud has recommended the use of a barium sulphide depilatory for the same purpose, and this is probably a quicker method. After the skin thickening has been reduced, Whitfield's ointment, either in normal or double strength, is applied as above. I have tried various other preparations—tinct. iodi, chrysarobin, mercurochrome-220 soluble, Castellani's fuchsine paint, and other preparations, but on the whole I am satisfied that Whitfield's ointment, if used conscientiously, is effective and less liable to cause complications than the other drugs. Whatever preparation is used, patience and systematic treatment is necessary to effect a cure. In those cases where a small crop of vesicles develop on the foot I have found painting with Castellani's paint gives good results. The small vesicles should be punctured and the paint applied night and morning. When the lesions are well I recommend three or four weeks' inunction with Whitfield's ointment.

It is important to remember that treatment must not be confined merely to the affected skin, but must be extended to the areas surrounding it. A. Strickler and W. H. McKeever (*Arch. Derm. and Syph.*, April, 1934, p. 526) have shown fungus in the skin from one to two inches beyond the affected areas.

The Nail's

The nails furnish us with a further problem. If these show clinical or microscopical evidence of involvement they should be dealt with. So great an authority as R. Sabouraud (*Med. Press and Circ.*, August 30th, 1933, p. 206) maintains that the only cure, when the whole nail is involved, is avulsion, followed by painting the nail-bed with 1 per cent. iodine in alcohol. Softening the nail with liquor potassae and scraping it away, afterwards applying antiseptics to the bed, can be used, but is more troublesome and less effective.

Recurrence

Having cured the clinical condition we still have to face the problem of recurrence. This may be due either to reinfection or to failure to kill the fungus in the skin in the first instance. Unfortunately, it is usually impossible to decide which it is; even the most careful microscopical investigations are not infallible. Knowing, however, how extensive the infection may be, and having carried out as complete a treatment as is possible, it only remains for us to try to prevent reinfection from the patient's footwear. While the patient is under treatment boilable socks should be worn next to the skin, and should be boiled frequently. When the disease is apparently cured it is best to destroy all old socks, and even then a boilable slip should be worn under the sock while any treatment is going on. Boots and shoes present a greater difficulty: if they can also be scrapped so much the better, but economic considerations cannot be entirely ignored. Short of destruction, swabbing out the boots or shoes with 2 per cent. formalin appears to be the most useful method of dealing with them.

By these methods we endeavour to prevent fungus from again becoming lodged on the feet. Can we further strengthen our defence by the use of substances which hinder the growth of fungus on the skin? O. C. Levin and G. H. Silvers (*Arch. Derm. and Syph.*, September, 1932, p. 466) find that the sweat in the fourth interdigital spaces of the feet is less acid than normal, and they believe that this encourages the growth of fungus in this region, admittedly the most common site of infection by fungi on the feet. They find that by dusting between the toes talc powder containing 1 to 2 per cent. salicylic acid the normal acidity of the sweat can be restored. It is no trouble to anyone to dust some powder between the toes each morning, and this appears to be a very useful method of diminishing the liability to reinfection. It should be continued indefinitely.

Prophylaxis

We now turn to consider the question of prophylaxis as applied to the population as a whole. Prophylaxis of foot ringworm presents very great difficulties for several reasons. It is a very common affection. It is difficult to say how common it is, because a large number of sufferers from it are unaware that they have anything wrong. Even those who notice some scaling or cracking between the toes consider it a normal event. It is certainly very common in private practice, and by no means so uncommon in hospital work as one is sometimes led to suppose. Further, even when one has pointed out to patients that they have this infection in a mild form it is exceedingly difficult to induce them to carry out a prolonged treatment for a condition which causes them no inconvenience. It is also a difficult matter, for those of us who treat these cases habitually, to say with any certainty that we have effected a cure with the methods at present available, and so long as any uncertainty on this score exists in the minds of the profession it diminishes its power in demanding protracted treatment from the patient.

Our first object in prophylaxis should be to remove all sources of infection. I have said that we have to face two difficulties: the failure of the public to recognize mild cases, and the difficulty of obtaining a certain cure. As regards the first of these difficulties, I can see no hope of slight cases coming for treatment in our present state of society. It would necessitate compulsory medical examination of the whole population and the education of the medical profession to recognize the condition, a stage which it has not yet reached. Before such a state of affairs has arrived, however, we may hope that dermatologists can offer a more successful and rapid cure of the

condition. Though it may take some time for the millennium to arrive, a great deal might be done, and in some places is being done, to diminish the dissemination of the disease by systematic inspection and treatment. It is well known that the disease is specially liable to spread in communities such as public schools, universities, sanatoria, etc. In these places systematic examination of the feet and treatment might be much more completely carried out than it is at present.

Assuming, therefore, as we must, that there are always a number of infected persons amongst us, we now have to consider how infection of the non-infected can be prevented. It is probable that most fungus infection is picked up by the toes from the floors of bathrooms, swimming baths, changing rooms, etc.—in fact, any place where infected persons may stand with bare feet and so leave scales about. There are two main methods of prophylaxis available: first, by preventing the naked foot from coming into contact with the floor, either by wearing rubber shoes or by having separate bath mats for each person; and, secondly, by using some antiseptic after contact with a possibly infected floor. For hotels and private houses the use of separate towels and bath mats would probably go a long way towards preventing infection, while the employment of rubber shoes in swimming baths might well be made compulsory. In America this question has been studied very carefully by a number of observers.

To quote only one published paper: R. T. Legge, L. Bonar, and H. J. Templeton (*Journal of the American Medical Association*, July 20th, 1929, p. 170), examining the feet of 3,100 entrants to the University of California in one session, found 53.3 per cent. of the men and 15.3 per cent. of the women had foot ringworm. At the end of a year they again examined 1,000 of these men and 997 of the women who had access to the showers, swimming pools, and gymnasiums. Of these, 78.6 per cent. of the men and 17.3 per cent. of the women were found infected. The increase in the case of the men is striking. The authors point out that the women students occupied a gymnasium with every known sanitary device. The women students and attendants were obliged to wear rubber shoes, and in no circumstances were they permitted to walk with bare feet on the floors or runways leading to the swimming pools or gymnasiums. On the other hand, the men occupied an antiquated gymnasium, where, on account of the lack or non-use of bathing shoes, and inferior sanitary facilities, the students constantly walked on their bare feet and became infected.

With regard to the use of antiseptics in public bathing establishments, these have been tried with considerable success in America. W. L. Gould (*Journal of the American Medical Association*, October 18th, 1931, p. 1300) recommends baths of 10 to 15 per cent. sodium thiosulphate solution to be placed in such a way that all users of the baths must walk through them on their way to their dressing rooms. E. D. Osborne and B. S. Hitchcock (*ibid.*, August 13th, 1931, p. 453) and E. D. Osborne, E. D. Putman, and R. J. Rickloff (*ibid.*, November 1st, 1933) in the same way use 1 per cent. sodium hypochlorite. Both claim to have prevented any spread of the disease by these methods. Needless to add, the proper flooring, and cleaning of dormitory floors, bathrooms, swimming baths, etc., adds materially to a reduction in the risks of spreading infection.

Conclusion

To sum up, we are dealing with a very common affection which, though it does not terminate fatally, and therefore appear in the Registrar-General's returns, may cause a good deal of suffering and loss of work. Owing to its insidious onset a great number of cases escape detection, and, even when detected and treated, for various

reasons do not get completely cured. We have to face the fact, therefore, that for the present there will be a large number of individuals infecting the floors of our private bathrooms, public bathing places, etc. I have pointed out that a good deal could be done to limit the spread of infection in such places, but in order to get such measures adopted on a large scale the public would have to be educated, and this can only be done through the medical profession, and the profession as a whole is still barely aware that the problem exists. Possibly the solution of the problem really rests with the dermatologist. I find myself very much in agreement with Weidman, who, in a discussion on the subject in America, made the following remarks:

"The hygiene of the problem is so complicated that I doubt whether the difficulty can be met by that route. It is impossible to sterilize all the wearing apparel of the patient; even so, there would still remain the floor coverings in our homes, hotels, shower baths, etc. It seems to me that the real approach to the millennium in the way of treatment is to establish conditions in the intertriginous locations in which the fungi work and mobilize, which will make these locations undesirable to the fungus."

May it not be that in this direction lies the solution of our problem?

MUCO-PURULENT TUBO-TYMPANIC INFECTIONS*

BY

T. RITCHIE RODGER, M.D., F.R.C.S.Ed.

SENIOR SURGEON TO THE NOSE AND THROAT DEPARTMENT,
HULL ROYAL INFIRMARY

When the president suggested for this discussion the subject of tubo-tympanic infections I understand he had in mind its limitation to the class of ear case in which we have reason to believe that the anterior part of the tympanum is mainly involved—cases in which the perforation, if any, is present, is demonstrable, is anteriorly placed, and the discharge, if any, is predominantly mucoid or muco-purulent. We have to include also, of course, cases of low-grade infection in which perforation of the membrane does not occur, although from the appearances, the impairment of function, and the auscultatory signs on inflation we are able to presume the presence of secretion in this part of the middle ear. Further, the president suggested that we might include in the category those unsatisfactory cases exhibiting a continued or recurring muco-purulent discharge from the anterior part of the cavity after the radical mastoid operation.

We are not directly concerned on this occasion with the acute otitis media arising in the course of common colds, influenza, and the exanthemata, nor with chronic otitis media showing more or less destruction of the posterior part of the membrane with perhaps granulations or polypus. The differentiation cannot be very rigid, however, as many cases properly included may have begun as conditions indistinguishable from the cases we are excluding, and may be looked upon as residuals from the latter.

Why should a middle-ear infection spend its energies on the anterior part of the cavity in preference to the posterior, or (as may be the more correct form of the question for some cases) why should the infection of the anterior part of the cavity continue when it has subsided in the posterior part?

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Infection by Direct Spread or by Blood Stream

We are probably all agreed that in the great majority of cases infection reaches the tympanum by direct spread along the Eustachian tube, whose mucous membrane is continuous with that of the nasopharynx on the one hand and the middle ear on the other. The fact that otitis media most commonly arises as a complication of influenza or a common cold, or of those of the exanthemata which in their early stages attack the upper respiratory tract, seems to make such a conclusion incontrovertible. It is comparatively seldom that we do not get a history of sore throat or nasal catarrh antedating the onset of the middle-ear signs. In a large group of cases the Eustachian tube serves merely as an avenue of approach, its inflammatory condition passing off as quickly and completely as the nasopharyngitis which was its precursor. The distinguishing point of the group we are considering to-day is that the Eustachian tube remains prominently in the picture.

On the other hand, there seems to be some basis for the view that sometimes the infection in otitis media, and particularly in mastoiditis, may be blood-borne and quite independent of the Eustachian tube. Killian held that infection of the paranasal sinuses in scarlet fever is blood-borne, and if so why not the mastoiditis which is much more common in this disease? The middle-ear complications of typhoid fever, said to occur in 7 per cent. of cases, are likely to be blood-borne, as nasopharyngitis is not a feature of this disease.

Some observers from experimental work on animals have concluded that pneumonia may be a blood-borne infection, and not an extension down the mucosa of the bronchial tree. They found the pneumococci in the blood during the incubation period, but when consolidation had occurred in the lung the organisms were found to have migrated there and the blood stream was free of them. The hypothesis is that when the pneumococcus gains entrance, usually by the pharynx, the alveolar tissue of the lung, for which the toxins of this organism have an affinity, becomes sensitized. At the end of the incubation period the pneumococci migrate to the tissue thus prepared for them. Possibly the same may occur in influenza and the exanthemata, in which diseases we have abundant reason to suppose that the causative organisms have a special predilection for the mucosa of the middle-ear cleft.

A few months ago I had an opportunity of observing more closely than is usually possible the onset of the ear symptoms in an extremely severe epidemic of measles in a preparatory school, and some of the cases were very suggestive of a blood-borne infection. The inflammatory signs appeared first in the posterior-superior part of the membrane, while the lower part retained its lustre, even as far as not to have lost the light reflex. When, after a few hours or, at most, a day or two, the redness extended over the whole membrane, and myringotomy was performed, only a thin serous fluid escaped. The mastoid operation was necessary in most of the cases in which myringotomy was done, and although it was never delayed beyond two or three days, the advanced stage of the mastoid disintegration suggested that the mastoid infection had antedated rather than post-dated that of the middle ear. The medical officer of the school, indeed, suggested a blood stream infection of another kind. He went very carefully into the history of all the boys affected, and found that most of those who developed mastoiditis had been contacts of another boy whom he suspected of being a scarlet fever carrier. This boy actually had, during the measles epidemic, a recurrence of suppuration in a mastoid operated upon after scarlet fever eighteen months previously. The theory, in which the medical officer is supported by a distinguished bacteriologist to whom he presented the data, is that these boys contracted a streptococcal mastoiditis from a latent scarlet fever infection when their resistance was lowered by measles.

However, while recording the opinion that in some cases an acute middle-ear or mastoid infection may be blood-borne, I am not suggesting that in this fact we have the distinction between tubo-tympanic infections and those involving the posterior part of the cavity. Probably only a comparatively small number of cases of otitis media can be even suspected of being blood stream infections. The Eustachian tube must be looked upon as the usual pathway of infection.

Why, then, should the infection sometimes confine its energies to the anterior part of the cavity and at other times skip this, or pass lightly over it, and produce a more severe condition, often with bone involvement, in the posterior part?

Variation of Mucosa in the Middle Ear

The variations in the mucous membrane distributed over the walls of the tympanum may provide part of the explanation. In the anterior part of the floor of the cavity and on its anterior wall where the Eustachian tube enters, the lining is of ciliated cylindrical epithelium. Over the promontory it is cuboidal-celled, and over the attic squamous-celled, this type being continued through the aditus into the mastoid antrum and further cells.

We know that particular organismal types show a predilection for one type of epithelium over another, so that the question whether an ear infection is to become a posterior and mastoid infection rather than one confined to the anterior part of the tympanum may depend on the particular organism involved. I have not been able to trace any bacteriological research into the types of organism predominantly found associated with anterior perforations—obviously the flora is likely to be very mixed by the time a case comes under observation—but it is well known that in the acute cases affecting the posterior part of the cavity and going on to mastoid operation, one or other of the many types of streptococcus is most commonly involved. We also know from clinical experience that the streptococcus is much more liable to attack the squamous epithelium of the pharynx than the ciliated epithelium of the nose. We are not surprised, therefore, to find it selecting for attack that part of the middle-ear cleft which is lined by squamous epithelium.

Degree of Virulence of Organism

There is also the question whether the degree of virulence of the organism, whatever its type, may determine the site of its action, or its maximum action, in the middle ear. Influenza varies enormously in its virulence in different epidemics, although presumably the same organism is always involved. In the milder epidemics just as we have fewer sinus suppurations complicating the nasal symptoms, so also in the ear we have the milder anterior type of otitis media predominating over the posterior more severe type. During the winter of 1925-6 we had, in my area, two distinct visitations of this disease, one in December and the other in March. The former was mild, and of the myringotomies I personally performed only 1 in 10 required the mastoid operation. In the later epidemic, which was a severe one in all respects, one-third of the myringotomies were followed by mastoidectomy.

We have the same variations in the virulence of other epidemic diseases. I looked up my old copy of Osler and Macrae's *System of Medicine* of twenty-five years ago and found the ear complications of measles thus described:

"An acute catarrh of the middle ear is not infrequent from extension of the inflammation in the nasopharynx along the Eustachian tube. It may cause earache, slight deafness, or tinnitus. Occasionally the inflammation becomes purulent and the ear drums rupture. Mastoid abscess rarely complicates the middle-ear disease."

If this represents the incidence of ear symptoms in measles in America at that period, the disease in this country at the same time must have been more fruitful of such complications, as a large proportion of the chronic otitis media cases we see among young adults and people of early middle age are stated to date from measles in childhood. Then in still greater contrast we have the recent very severe epidemic which occurred in several parts of this country with an unusually high incidence of mastoid complications. In the small school epidemic I have already referred to the ears were affected in nearly 50 per cent. of cases, and of the affected ears nearly 50 per cent. required the mastoid operation.

There seems, therefore, to be some ground for thinking that the degree of virulence of an infection may determine the question whether one part or another of the tympanum is more likely to be affected.

Changes in the Floor of Middle Ear

There is also the question whether, owing to the dependent position of the floor of the middle ear, changes ulcerative or otherwise may occur in the mucosa, tending to chronicity. An analogy is to be found in the anterior inner angle of the maxillary antrum, where the mucosa is so frequently polypoid and unhealthy to a degree greatly in excess of any changes present in other parts of the cavity.

Professor Nager holds the view that the anterior perforation with mucoid discharge frequently indicates a tuberculous ulceration of the mucosa, and that this is often proved by the history, by von Pirquet's reaction, and by the presence of the scars of broken-down glands.

The Eustachian Tube

Then we have to reckon with the possibility of pathological changes in the Eustachian tube itself, keeping up an infective discharge from it into the middle ear—the so-called tuborrhoea. The Eustachian tube consists of three parts—a short upper end enclosed in a bony canal, a longer lower end in a cartilaginous funnel, and, between, a short isthmus, supported only by fibrous tissue. In this middle part the walls of the tube are in contact except when, by the act of swallowing, air is forced up the tube into the tympanum. Theoretically, after an acute inflammation of the tube, ulceration and consequent adhesions in this area might produce a condition analogous to stricture of the urethra and gleet, and it is possible that some of the rare cases in which inflation of the ear through the tube cannot be achieved may be so explained. What is still more likely to occur is that after an inflammatory condition in the tube has been established for some time the epithelium loses its cilia, as happens in similar circumstances in the nose and nasal sinuses, and this is probably the explanation of the persistence of tuborrhoea in those disappointing cases which resist treatment in every form.

The Nasopharynx

I am strongly of the opinion, however, that most frequently the determining cause of tubo-tympanic infections is not to be found in the particular organism concerned, nor in its degree of virulence, nor yet in any chronic or permanent change in the mucosa of the floor of the middle ear or of the tube, but in some pathological condition beyond the lower limit of the tube. The original cause and, in most cases, the continuing cause of an unhealthy Eustachian tube is to be looked for in its adnexa—the nasopharynx, the nose, or the paranasal sinuses—and it is mainly there we have to direct our attention with a view to the cure and the prevention of the condition we are discussing to-day.

The Question of Adenoids

As far as children are concerned—and the bulk of our cases of tubo-tympanic infections occur in children—sepsis and hypertrophy of the adenoid tissue of the nasopharynx take first place. It might almost be called the Golden Rule of Otology that in every case of ear discharge or catarrhal deafness in children the question of adenoids must be investigated, and yet one is constantly seeing cases in which the rule has been forgotten over a long period of local treatment.

I have described, in a communication read elsewhere, how when I started an aural clinic in connexion with a school medical service eight years ago I had at first to deal with scores of cases which had attended for local treatment of the ears for long periods, sometimes for years, and which cleared up in two weeks or less after removal of adenoids. No doubt everyone present has had a similar experience, and is finding it still repeated, although, happily, in diminishing degree.

The question of the presence or absence of adenoids should be settled in every case—without qualification. It is not sufficient to accept the mother's statement that there is no snoring or mouth breathing. Nor must we be satisfied with an assurance that the tonsils and adenoids have been removed—not even if we have done the operation ourselves. Even if inspection of the pharynx shows that the tonsils have been completely enucleated we have no right to assume, without an adequate view in the mirror, or, failing that, palpation with the finger, that the nasopharynx is equally free from excess of lymphoid tissue. Many operators seem to be more careful about the efficiency of the tonsil part of the operation than about the complete removal of the adenoids, and do not trouble to finish up with the finger after the curette, to make sure that everything has been removed, especially in the region of the Eustachian orifices and the choanal entrances. Apart from this, no one can guarantee that adenoids will not recur even after efficient removal. In the case of the tonsils, if we remove the capsules completely we can promise that they will not grow again, but we can give no such guarantee as regards adenoids, of which we merely scrape away the excrescence. It is true that recurrence after complete removal does not often take place, and that when any considerable mass of adenoids is found after a previous operation, examination of it generally proves it to be virgin tissue which has obviously escaped the curette before. It is not uncommon, however, to find an overgrowth of unhealthy granulations in the adenoid area—and the child with a chronic or recurring ear discharge cannot afford to harbour anything unhealthy in the vicinity of the Eustachian tube.

With a view to the prevention of a chronic tubo-tympanic infection it is equally necessary to keep this question of adenoids prominently before us in every case of acute otitis media. To embark on the local treatment of an acute ear which has spontaneously ruptured, or to do a myringotomy or mastoid operation where such is indicated, without making sure whether or not the nasopharynx is free from the sepsis or obstruction of adenoid tissue, is not giving our work the best conditions for success.

I have made it a rule for some years that every case of acute mastoiditis admitted to the children's ward must have adenoids removed a week or so after the emergency operation if any adenoids at all are present. If on examination before the mastoid operation the tonsils are found to be healthy or to have been removed, it is a good plan to palpate the nasopharynx at the close of the mastoid operation. If adenoids are present they can be scraped away there and then without adding

appreciably to the patient's discomfort. If, however, the tonsils also require removal, the combined tonsil and adenoid operation should be done within a week, so that the length of stay in hospital is scarcely prolonged. The same applies to cases admitted for myringotomy—adenoids alone may be removed when the myringotomy is done, or the complete tonsil and adenoid operation is done a week later if the tonsils also require removal. I believe that by this procedure cases of prolonged discharge after the mastoid operation or after myringotomy are reduced to a minimum.

Before leaving the question of adenoids perhaps a word should be said about the part the tonsils may play in keeping up a Eustachian tube catarrh. It is admittedly a very minor role compared with that of adenoid growths, but it is obvious that the proximity is close enough to demand consideration. Unhealthy tonsils must predispose to a nasopharyngitis, and so to the enlargement of adenoids or the growth of granulations where adenoids have already been removed. One generally finds in young people that with imperfectly removed tonsils adenoids or granulations are also present. This may, of course, only mean that the adenoid removal has been as badly done as the tonsillectomy, but it may also mean that recurring inflammation in the tonsil stumps leads to hypertrophy in the upper part of Waldeyer's ring. On the whole, I think on these grounds it is better to remove unhealthy tonsils in tubo-tympanic infections.

Relevant Intranasal Conditions

Let us now consider conditions in the nose itself which may cause or predispose to Eustachian tube infections.

1. *Foreign bodies* may cause a persistent rhinitis. Some time ago I saw a boy of 9 years with a history of recurring otorrhoea since babyhood. Conservative measures seemed to be successful for short periods, and particularly encouraging for a time after the removal of tonsils and adenoids, but recurrence always took place. I found a bead in the middle meatus of one side of the nose, and after its removal the ear quickly dried up. As a boy of 9 is not likely to put a bead in his nose, we presumed that the foreign body had been there as long as the ear discharge had lasted.

2. *Nasal obstruction* interferes with the efficient ventilation of the Eustachian tubes, and so predisposes to tubal catarrh. The most common cause of such obstruction in adults is a deviation or spur of the septum. In addition to blocking the airway, indeed sometimes without much blocking at all, this gives rise to a post-nasal phlegm, which trickles back over the spur and collects in the nasopharynx. The spur or knuckle causes contact of surfaces which should not be in contact, and produces a kind of nasal intertrigo with irritation of the mucous glands. In a case of tubo-tympanic infection the examination of the nose should be conducted with thoroughness. Cocaine and adrenaline should be applied in every case, as the spur is frequently situated far back and not visible to a casual examination without shrinking of the mucosa. We shall, in any case, probably want to test the patency of the Eustachian tube with the catheter, and the preparation with cocaine will not come amiss for that procedure. A septal deformity is so easily corrected that if we conclude that it has a bearing on the case there can be no excuse in most cases for leaving it untreated. Palliative measures are unsatisfactory. The operation can be done with local anaesthesia, with or without a previous medication sufficient to put the patient to sleep. A mucilage of cocaine with adrenaline added is painted carefully over every part of the septum on both sides, and the sphenopalatine ganglion is blocked by the application of a single drop of 99 per cent. cocaine held against the ganglion for one minute on a cotton-wool

mop. This should be done just before commencing the operation, when the localizing effect of the adrenaline already applied prevents absorption of the strong solution of cocaine. The operation is then practically bloodless, and if we discard post-operative plugs and merely paint the wound and the septal mucosa with Whitehead's varnish, discomfort is reduced to a minimum.

3. *Nasal polypi*, besides being a frequent cause of nasal obstruction and interfering with the due ventilation of the Eustachian tube in the same way as do septal spurs, have an added danger in so far as they are always associated with some degree of sepsis in the ethmoid or other paranasal cells. The discharge bathing the nasopharynx is therefore more pathogenic than the phlegm associated with septal deformity. In the kind of ear case we are considering nasal polypi should always be removed, and an attempt made to eradicate the sepsis from which they arise.

Sinusitis

Apart from the obstruction caused by polypi, any of the paranasal sinuses may by its being the seat of suppuration—that is, without polypus-formation—cause or keep up an infective condition in the Eustachian tube. I have recently given more attention than I had previously done to this relationship, and have found so many cases in which the antrum of Highmore especially was infected, not only in cases of recurring ear discharge, but in acute cases demanding myringotomy, that I have come to the conclusion that no examination of an inflammatory ear, either acute or chronic, is complete unless it includes the most thorough investigation of the nasal sinuses. Transillumination is admittedly unreliable and should be depended upon only if it yields on both sides an equally bright infra-orbital crescent and pupil illumination, and if there is no suggestion of pus or boggiess in the middle meatus. If there is the slightest doubt x-ray examination or exploration should be resorted to. I have several times in recent months when called to do a myringotomy on an acute ear found an antrum opaque on transillumination, and have washed out pus from it under general anaesthesia after doing the myringotomy. If, after inserting the trocar, the patient is placed so that the face is turned three-quarters downwards over the edge of the table there is no danger of fluid passing into the trachea. Such acute cases do not properly come into our discussion to-day, but are admissible from the point of view of prevention, as it is extremely likely that a large proportion of them would not clear up after myringotomy, but would drift into the class of tubo-tympanic catarrh if the nasal sinus were left untreated.

Further Points In Treatment

I quite expect that some will disagree with me over this question of treating an infected antrum in an adult or removing adenoids in a child at the same time as the operation for myringotomy. I make no point of it, but I find it works. The essential point is not to miss anything in the nose or nasopharynx which may be either an exciting or a predisposing cause of the ear condition, and to make sure that it is effectively treated in good time so as not to prejudice our direct treatment of the ear. Septal deflections, polypi, and ethmoid or frontal sinus conditions should be treated as soon as the acute condition in the ear has been relieved.

We must not allow ourselves to be hesitant at doing less than restoring the environs of the Eustachian tube to a condition as near to the ideal as surgical measures or other treatment will achieve. We may have prejudices to overcome, as the patient—and sometimes the practitioner—may not appreciate the connexion, but it is our business to educate them. It has taken almost a genera-

tion to teach the public the relation between adenoids and ear suppurations. It may take as long to convince people that anything at all interfering with the proper ventilation or assepsis of the Eustachian orifices is of scarcely less importance.

Special mention should now be made of the less frequent case in which the middle-ear infection is so mild that rupture of the tympanic membrane does not occur and the changes visible in it are not such as seem, judging by the ordinary standards, to demand myringotomy. The subjective signs may be a feeling of fullness or wooliness in the ear with a greater or less degree of deafness, and perhaps crackling noises. Pain is not severe and may be absent altogether. On objective examination the tympanic membrane may be a dull red or only lustreless. Bone conduction may be greater than air conduction, but only if the deafness is of considerable degree. Diagnostic inflation, by the catheter with the aid of the otoscopic tube, is our most reliable guide, and may reveal some blocking of the Eustachian tube and some whistling rales suggestive of moisture in the tube, or finer bubbling rales indicative of fluid in the tympanum, or both kinds of rales may be heard. There is nothing in the condition at first to distinguish it from a mild catarrhal otitis media, such as might pass off in a few days without treatment, but in spite of inhalations and repeated inflation it persists. Probably most of us have occasionally watched these cases for weeks. I think we should intervene earlier—doing a myringotomy under strict aseptic precautions and inflating by the catheter immediately afterwards to expel through the incision the thick mucoid discharge. The patient will, in most cases, be able to continue the expulsion by Valsalva's method. I shall quote only two cases as examples.

H. W., a male aged 57, had had ticking and singing noises in the right ear for one month; the membrane was injected and lustreless, bone conduction was increased, and a whisper was not heard close up. Bubbling noises were heard on inflation, using the otoscope. Inhalations and catheterization were employed for five weeks without appreciable improvement. Myringotomy was then performed, and while he was still under the anaesthetic the Eustachian tube was catheterized. Sticky muco-pus was ejected, and on mopping appeared like a glistening bead on the cotton-wool. The ear was kept clean by boric acid in spirit and the opening remained patent for twelve days, the blow-through sounding dry for a few days before closure. By that time a whisper was heard at 12 inches, but it took two months for complete restoration of hearing. I am of the opinion that had myringotomy been done two or three weeks earlier recovery of hearing would have been more rapid. In this case a marked deflection of the septum was the probable predisposing cause, but in view of his age I did not suggest operation. In this class of case, however, as in the frankly suppurative cases, any abnormal condition in the nose or nasopharynx should be attended to.

The second patient was a female, aged 60. The right ear had been completely deaf for many years, the tuning-fork tests indicating a nerve deafness. Recently the left ear had also become quite deaf, following on a complete blocking of the nose, from what her medical adviser took to be an allergic condition. The membrane was lustreless but not bulging, bone conduction was increased, and a whisper was not heard close up. Both antra were dim on transillumination and yielded copious pus on lavage. Inflation of the left Eustachian tube revealed bubbling after initial blocking was overcome, and the hearing was greatly improved. After lavage had been repeated five times the nasal airways were good and the hearing restored to normal, but the antra still yielded some pus. There could be no question in this case about the connexion between the antral suppuration and the tubo-tympanic catarrh.

It remains to me to refer to the question of otorrhoea after the radical mastoid operation. Even in the hands of the best operators a certain proportion of operations

fail to achieve complete cessation of the discharge, and it is generally the anterior end of the cavity that is at fault. As a rule, on inflation by Valsalva's method, muco-pus appears at the Eustachian tube end, indicating that, despite all our care in curetting or cauterizing, nature has not favoured us with complete atresia of the upper end of the tube. The operation is not a failure, but it may appear to the patient as such. We are satisfied that we have excavated the cells of the danger area and put the patient in a position of safety, but he was probably more concerned about the annoying discharge, and this continues.

In these cases also, may it not sometimes be the other end of the Eustachian tube we have neglected? Every case of chronic otorrhoea should be carefully studied from every point of view before the mastoid operation is undertaken, and if there is anything in the nose or nasopharynx which might interfere with the health of the Eustachian tube correction of this should be included in the scheme of treatment. If the case is not urgent, I begin with the minor conditions while instituting careful intensive local treatment of the ear, and one is quite frequently surprised to find that the mastoid operation is not required although long periods of local treatment have hitherto been unsuccessful, the case thus proving to be mainly a tubo-tympanic infection when it had all the appearances of a chronic mastoiditis. If the discharge does not dry up we go on to the mastoid operation with confidence that everything is in as good train as may be for a satisfactory outcome. In the numerous cases in which pain, pyrexia, or other signs indicate the need for an immediate mastoid operation, the unhealthy condition in the nose or nasopharynx should be rectified as soon as the patient is fit. Here again, as in the cases referred to earlier, the length of stay in hospital is not prolonged if the minor operations are timed to take place about a week after the mastoidectomy.

Concluding Remarks

In conclusion, I do not wish to seem to minimize the importance of the local treatment of the ear—this must be assiduous as long as may be necessary. I favour the dry treatment as a rule, doing intratympanic irrigation or meatal syringing only as often as is required for removal of debris. After each irrigation the middle ear and meatus should be completely dried by successive mops, aided by catheterization or Valsalva's method. The meatus is then filled with dry boric powder or with the powder suspended in spirit. Nor do I belittle the help that some claim to get from intratubal treatment, but I think the centre of gravity lies at the other end of the Eustachian tube, and that the nasopharynx, with its adjacent cavities, should be explored in every case of tubo-tympanic infection.

In its latest publication, *Standard Code of Industrial Hygiene*, the International Labour Office turns its attention to the lot of workers employed in factories, workshops, etc., who, without incurring specific risks, are nevertheless exposed to the dangers resulting from unhygienic working conditions. There are forty-six clauses in the *Code* covering all matters affecting the health of workers in premises at and above ground level, workrooms below ground level, work under shelters, pent-houses, etc., and unhealthy or offensive trades. It is not intended that the *Code* should serve as a standard system of regulations for general adoption, but rather as a guide for those concerned with the health of the industrial worker. The pamphlet may be obtained from the publishers, P. S. King and Son, Ltd., Orchard House, Westminster, S.W.1, price 1s. 6d.

ELECTRO-COAGULATION OF THE PROSTATE

IMMEDIATE AND LATE RESULTS

BY

HERBERT WILLIAMS, M.B., F.R.C.S.

SENIOR HONORARY SURGEON, ROYAL SOUTHERN HOSPITAL, LIVERPOOL;
LECTURER ON CLINICAL SURGERY, UNIVERSITY OF LIVERPOOL

Perurethral methods of treating prostatic obstruction, though still in their period of trial, are undoubtedly finding a place in the field of surgical therapeutics. I feel, therefore, that a report on a short series of cases, most of which were operated on over five years ago, is of interest, and particularly so from the point of view of later results. The method of operating used in this series is one that I evolved as a result of experimental work in 1926, and first put into use in February, 1927.

The technique is described in the *British Medical Journal* of December 8th, 1928, and what I am writing now is supplementary to what I then wrote.

Technique

Briefly, the technique entails the use of two instruments (Fig. 1):

1. *The Diathermy Catheter*, with a coude bend and a small metal tip, which can be activated from a diathermy machine. It is used for filling and emptying the bladder and for coagulating the tissue that is causing obstruction of the vesical orifice. The manipulation of this instrument is controlled by vision through:

2. *The Suprapubic Cystoscope or Prostatoscope*.—This latter instrument is introduced into the bladder by suprapubic puncture. Through it a clear view is obtained in one field and from above of the whole vesical orifice and its surrounding abnormalities (Figs. 2 to 5).

By the combined use of these instruments any obstruction that may be encroaching on the vesical orifice can be clearly visualized and coagulated with selective precision. Since the technique was first introduced I have made two modifications:

1. The original diathermy catheter was insulated with a cover of boilable lacquer. This insulation was found to be inadequate. The minutest crack in the lacquer allowed the current to leak and cause a burn of the urethra. I have had two cases of papilloma of the bladder in which the technique described above was being used, where the urethra was burnt in this way—one slight, and the other extensive and serious. The risk of this occurring has now been eliminated by covering the lacquer with a thin metal sheath. This serves the double purpose of protecting the lacquer, and, should a leak occur, the whole length of the

instrument becomes warmed, and no damage is caused to the urethra.

2. Before withdrawing the sheath of the suprapubic cystoscope a piece of rubber tubing is passed through it into the bladder for drainage. This is a valuable modification of the technique, for it acts as a safety valve should the catheter become blocked; it lessens the risk of pre-vesical cellulitis; it provides an effective way of irrigating the bladder for as long as is necessary after the operation, and helps very materially to combat the effect of sepsis. The fistula will close in two to four days after the removal of the tube.

Choice of Cases

All cases with undoubted and persistent symptoms of prostatic obstruction, in which on rectal examination the prostate was large, smooth, and movable, and in which the clinical condition and renal functions were satisfactory, have been submitted to suprapubic prostatectomy. The remainder, provided they were not obviously moribund, were treated by electro-coagulation.

It will thus be realized that the technique has been put to a severe test, and this should be taken into account in assessing its value as judged by results. The ages of the patients have varied from 50 to 84 years, and the duration of symptoms from two months to ten years. Frequency was present in all the cases, and eighteen had varying degrees of incontinence. No fewer than twenty-five cases had retention of urine on admission to hospital.

This high figure is accounted for by the fact that many of the cases were admitted as emergencies into a Poor Law hospital, where the proportion of such cases is high as compared with those with less acute symptoms.

Physical Examination

The usual general survey of the patient was made. In the selection of suitable cases for electro-coagulation rectal examination is of the utmost importance. Those cases with marked enlargement and prominent bulging into the rectum are best treated by prostatectomy. Cases suitable for electro-coagulation are those where the prostate is only slightly enlarged, those where the enlargement is chiefly in an upward direction, and those in which the prostate is smaller than normal.

In this series twenty-one were noted as being larger than normal, eleven as being smaller than normal, and the remainder normal. Residual urine varied from two ounces to complete retention. Pyuria was present in nineteen cases. The blood urea was estimated in all the cases except seven.

FIG. 1.—The cystoscope should have been shown as entering the bladder nearer the pubic symphysis and in a vertical direction.

The results are shown in the following table:

Blood urea in mg. per 100 c cm.	30-39	40-49	50-59	60-69	70-79	80-89	90-99	Over 100
No. of cases	8	5	11	3	2	2	3	1

Perurethral Cystoscopy

Wherever the diagnosis of prostatic obstruction was reasonably clear cystoscopy was not carried out. In the main the cases that did not require this examination were those with definite enlargements and those that had been admitted with retention and had been relieved by

were noted. These observations were of considerable value in the small or slightly enlarged prostate, and gave definite evidence as to the portion of the vesical rim that was causing the obstruction and required coagulating. I found it impossible to estimate with any degree of accuracy the size of the prostate by perurethral methods, and much more dependable information on this point was obtained by rectal examination and by using the suprapubic cystoscopy.

In brief, the value of perurethral cystoscopy and urethroscopy, where this technique is used, is to show that there is no obstruction in the urethra other than in

FIG. 2.—The normal vesical orifice.

FIG. 4.—Case 31. Bilateral and commissural enlargement. Electro-coagulation. Normal relief.

FIG. 3.—Case 5. Bilateral and middle lobe enlargement of the prostate. Treated by electro-coagulation. Normal relief.

FIG. 5.—Case 40. An enlargement of the right lateral lobe being coagulated. Normal relief.

catheter. In cases where the symptoms had some atypical features, and where the prostate, on rectal examination, was small, cystoscopy was as a rule carried out. The type of cystoscope used was one allowing of prismatic and direct vision.

A general survey of the bladder and trigone was made. Trabeculation was particularly looked for, and calculus and tumour were excluded. Attention was now directed to the prostate itself, and any gross finding noted. The experimental practice of plotting out a series of cystoscopic fields, and from these making a composite picture, was given up early in the series, for it was found that the information obtained was not worth the trouble it entailed and the extra intraurethral manipulation that the investigation involved. Before withdrawing the sheath of the cystoscope a direct-vision telescope was inserted, and as the instrument was withdrawn the contour of the vesical orifice and the encroachments on the prostatic urethra

the prostatic portion and at the vesical orifice, to exclude other conditions of the bladder that might account for the symptoms, and to ascertain if there is trabeculation of the bladder as indicating obstruction of the urinary outflow. It may be taken as an axiom that if there is trabeculation of the bladder and no stricture of the urethra, there is obstruction at the vesical orifice, however unconvincing the signs may be from perurethral cystoscopy and examination of the prostate itself.

Immediate Results

The convalescence of these cases has in the main been uneventful and free from anxiety. While the suprapubic drainage tube and the catheter drained the bladder the patients were comparatively comfortable. After these had been removed, and up to the end of the third week after operation, they complained of varying degrees of bladder irritability—frequency, precipitant micturition,

and dysuria. During this period the sloughs are separating, and as a rule they come away in small fragments and are passed per urethram without any difficulty. There has been a remarkable absence of haemorrhage, which is a striking contrast to what occurs in the resection and punch operations. In no case has there been primary haemorrhage. Trivial secondary haemorrhage occurred in three cases; in none of these did it last more than forty-eight hours, and it ceased entirely after the passage of fragments of slough.

Incontinence occurred in six cases. In all of them it was temporary. In one case the cessation of the incontinence coincided with the passage of a medium-sized slough. Inflammation round the vesical orifice and consequent dysuria is to be expected after treatment by perurethral methods. In ten cases it was more marked than usual, and lasted for varying periods up to three months. Epididymitis occurred four times—bilateral in one and unilateral in three instances. The inflammation cleared up in all cases with expectant treatment. In seven cases large sloughs formed, giving rise either to difficulty in micturition or to temporary retention. In five of these the slough was passed naturally, with great relief to the patient. In one case it was evacuated by means of a Bigelow's evacuator, and in the remaining case it was removed in the jaws of a small litholite after being crushed, the procedure being controlled by means of the suprapubic cystoscope.

Prevesical suppuration occurred in two cases. The first was the tenth of the series. The suppuration was extensive, and a suprapubic incision had to be made to evacuate a large quantity of pus. All cases after this one have had a tube inserted into the bladder, and only one case of this complication in a mild form has occurred since.

Remote Results

All the cases that are here reported were operated on during the five years 1927-31. In twenty-nine cases it is more than five years since the operation, and in the remaining thirteen from two to five years. The following table gives an analysis of the results.

Normal relief	50	per cent.
Partial or temporary relief	22.2	" "
No relief	11.1	" "
Died...	16.6	" "

Not traced: 6 cases.

For the purpose of this classification "normal relief" means that the patient passes his urine in a good stream, has no frequency and no dribbling, and does not get up to micturate more than once in the night. This is a very high standard of relief, and were it lowered a little the number in this category would be considerably higher.

Partial Relief

In this group six cases derived very considerable relief from the operation, but could not be classified under "normal relief" because frequency, though diminished, was still present. The following two had marked relief for a period, and then the symptoms returned.

Case 32.—Kept well for two years, when symptoms began to return. X-ray investigations showed stone in the lower end of the left ureter and a medium-sized stone in the bladder. Three months after return of symptoms the patient was operated on elsewhere. The left ureter was opened and the stone pushed into the bladder, which was then opened, the stones being removed and the prostate enucleated piecemeal with difficulty; the patient died on the fourth day after the operation.

Case 35.—Had marked relief for three years; then his symptoms began to return. Three and a half years after the electro-coagulation a suprapubic prostatectomy was carried out elsewhere. There was no difficulty in enucleating the prostate. The patient died the sixth day after the operation.

Unrelieved Cases

Three examples of this group are given below.

Case 14 was 84 years of age, and in a very feeble condition. Electro-coagulation gave him slight relief, but he returned in fifteen months with retention of urine. No further operation was done, but he improved after being catheterized for a few days. Twelve months later he "died of old age."

Case 16.—Had had frequency and incontinence for ten years before admission. The incontinence continued in spite of two electro-coagulation operations, one eleven months after the other.

Case 34.—Had two friable stones removed by litholapaxy at the same time as the electro-coagulation. He was readmitted twelve months later with a recurrence of symptoms, when prostatectomy was carried out and another stone in the bladder removed. He died three months later.

Causes of Death

There were six deaths in the series.

Case 6.—Was admitted with clinical signs of uraemia. He had a large prostate with bilateral and commissural enlargement. Blood urea, 75 mg. per 100 c.cm. During the fourth week after the operation his blood urea was up to 180 mg. per 100 c.cm., and he died of uraemia. (This was an early case in the series, and my enthusiasm rather warped my judgement. This patient should not have been operated on, as his trouble was too far advanced.)

Case 19.—Ten days after operation this patient passed urine freely and had no residual; could hold urine for five hours. Nine weeks after operation he had repeated attacks of epistaxis, from which he died a week later.

Case 21.—This patient was 80 years of age, and had suffered from diabetes for several years and haematuria for three months. His blood sugar was 333 mg. per 100 c.cm., and his blood urea 52 mg. per 100 c.cm. The blood urea went up to 85 mg. per 100 c.cm. on the seventh day after the operation, and on the eighth day he became comatose and died.

Case 26.—Had marked cystitis at the time of diathermy and twelve small vesical calculi, none of which was larger than a small pea. He died on the third day after operation, and the post-mortem examination showed an ascending pyelonephritis.

Case 28.—Admitted with retention of urine and a history of having had incontinence for six months. A small adenoma growing from the right side and filling the vesical orifice was destroyed. His convalescence was normal. On the eleventh day he was emptying the bladder completely without any difficulty. During the fifth week after the operation he became insane, and had to be transferred to a mental ward, where he subsequently died.

Case 29.—Admitted with chronic myocarditis, cystitis, and incontinence of urine. Electro-coagulation of left lobe was done. He had marked cystitis, which began to improve after the eighth day. It never completely cleared up. His cardiac condition became worse, and he died on the thirty-seventh day after the operation.

These cases illustrate in a striking manner what bad risks many of the patients in this series were. Case 26 was the only death that was directly attributable to the operation. In the light of subsequent experience I do not think this patient was suitable for treatment by this technique. A cystotomy was the only procedure that was feasible in his case. It seems unreasonable to blame the technique for the death of Case 21.

Untraced Cases

The untraced cases call for no comment. The immediate results were no better or no worse than the average, and there is no reason to think that had it been possible to trace them they would have materially affected the statistics.

Summary

1. By means of the technique described above the whole of the vesical orifice and its immediate surroundings can be seen in our field, and any tissue obstructing the orifice can be destroyed with selective precision.

2. The method has been put to a very severe test, inasmuch as all cases that were not suitable, or were in too bad a condition, for suprapubic prostatectomy were, provided they were not moribund, treated by it.

3. The immediate and remote complications and results are described.

4. Normal relief was obtained in 50 per cent. of the cases, and this standard of relief has been maintained for over five years. By using a little discrimination in the selection of cases, and with increasing experience, the proportion of cases enjoying normal relief would probably exceed 80 per cent.

5. The death rate directly attributable to operation by this technique is very low, even when the worst possible risks are dealt with. By eliminating the very bad risks it can probably be reduced to less than 1 per cent.

RESIDUAL INFECTION OF THE JAWS

BY

R. S. TAYLOR, M.R.C.S., L.D.S.

HONORARY DENTAL SURGEON, SEAMEN'S HOSPITAL, ROYAL ALBERT DOCK,
AND NATIONAL HOSPITAL, QUEEN SQUARE

"Residual infection" is a term employed in dental surgery to describe an obscure and indefinite condition occasionally met with in edentulous mouths, or in areas from which teeth have been removed. The condition has recently aroused much interest, but as yet the bone pathology has received little attention. It is proposed in this paper to review the pathology, aetiology, and treatment of residual infection with reference to cases which have come under the writer's personal observation.

The Condition Described

Clinically, a case of residual infection presents certain definite features. The patient is unwell himself, and has the appearance of a mild toxæmia; he is easily tired, and finds difficulty in concentrating his attention on any one subject for a prolonged period. When the upper jaw is affected antral disease is frequently present, and rheumatic pains and digestive disturbances are common. On examination the mucous membrane covering the affected ridges is found to be red and inflamed, and a number of pin-point ulcers, white in colour, are sometimes noted. The area is tender and the underlying bone may be rough, especially in the lower incisor region. The x-ray appearance is difficult to describe. In the lower incisor region the appearance may be that of an excrescence, while in the upper jaw the usual appearance is one of ill definition of the bony trabeculations.

The final diagnosis is made by culturing organisms taken from the affected region by means of a small round-headed dental burr, which is dropped into a broth tube. Cultures from positive cases are generally pure, and the infection is most frequently streptococcal in nature.

These patients have usually had very badly infected teeth, which have been removed by forceps. The infected bone has not been removed, and, because of poor resistance on the part of the patient, or as a result of some other factor, resolution of the alveolar bone does not take place, and the condition of chronic infection becomes established.

Treatment

The condition requires treatment not only of the local symptoms, but also of the general debility. Medical diathermy has been recommended, but in the writer's experience it does not produce a permanent cure. Operative treatment can be very satisfactory if it is thorough, but the mere removal of any bony excrescence is not sufficient. This may relieve dental discomfort, but will not benefit the patient's general health. It is essential to

remove as much as possible of the septic bone, while maintaining the shape of the alveolar ridge to assist in the subsequent fitting of dentures. When there is widespread infection of bone the operation may be done in several stages, using a local anaesthetic. It may, however, be more satisfactory to give an intratracheal anaesthetic.

A horizontal incision is made in the muco-periosteum on the outer side of the ridge, approximately midway between the crest and the sulcus, and the muco-periosteum is reflected from the ridge and held aside. With a sharp chisel the outer compact layer of bone is pierced, giving access to the cancellous portion. The soft bone lying between the outer and inner alveolar plate is curetted away and the resulting cavity swabbed out with acriflavine in normal saline (1 in 1,000). The area is then packed with acriflavine in glycerin for a period of five minutes. This produces a hyperaemia, and, in consequence, the tissues are thoroughly flushed out. All sharp edges of bone are trimmed off and the soft tissues carefully sutured in place.

Post-operative treatment consists of rest for several days after the operation. A mildly antiseptic mouth-wash is used every four hours, and pain can be controlled by the use of aspirin. A plaster of hot antiphlogistine, applied externally to the face, is very soothing. The sutures are removed on the fourth day, and pain and swelling have usually gone by the seventh. Dentures may be fitted in approximately four weeks after the operation.

Case Records

The following are four selected cases which illustrate the results obtained.

Case 1.—The patient had suffered from ill-health for many years, the chief trouble being arthritis of the hip-joint. He had had antrum, appendix, and teeth operated upon. For two years after the removal of the teeth his dentures were troublesome. X-ray examination showed the bone in the lower premolar, lower central incisor, and upper molar regions to be abnormal. A spear-point culture from the lower incisor region gave a growth of *Streptococcus haemolyticus*. At operation soft bone was removed from the affected regions. Three months after the operation dentures were fitted. These proved comfortable, and the general health was better.

Case 2.—The patient was suffering from bilateral antral empyema of fifteen years' duration. The radical operation had been performed and all the teeth extracted ten years previously. When the antral cavities were washed out pain was felt in the molar regions. X-rays showed dark areas in the upper molar and premolar regions. Spear-point cultures gave growth of *Streptococcus haemolyticus* and *Staphylococcus aureus*. The infected areas were curetted, and within two months the discharge had ceased and dentures were fitted.

Case 3.—The patient had bilateral antral disease, and the ridges of the upper jaw were tender to pressure. X-ray examination showed abnormal bone in the upper premolar and molar regions. The outline of the tooth sockets could be seen in the incisor region. Spear-point culture gave growth of *Streptococcus haemolyticus*, non-haemolytic streptococcus, and *Staphylococcus aureus*. A quantity of diseased bone was removed and the antral disease cleared up.

Case 4.—The patient had suffered from sciatica for more than a year, and manipulative treatment had given no result. X-ray examination revealed areas of bony rarefaction in the upper right first premolar region, this tooth being absent. Spear-point culture gave *Staphylococcus aureus* in pure culture. The affected area was curetted and a vaccine was prepared from the culture. Three months later the sciatica was gone, and the patient was enjoying normal health.

I wish to acknowledge indebtedness to Dr. Hanschell and Mr. Walters for facilities for laboratory work, and to Captain W. A. D. Drummond for assistance on the clinical side.

Clinical Memoranda

CYST OF THE THYMUS IN A NEWBORN BABY

According to the literature tumours of the thymus gland appear to be of extreme rarity. Osler quotes that not more than a hundred cases have been recorded. The commonest types of tumours seem to be sarcomatous in nature, while cysts have been regarded as being syphilitic in origin.

I recently encountered a case of cyst of the thymus gland which is sufficiently interesting to warrant publication.

On June 21st, at 9 p.m., I delivered a patient of an apparently healthy full-time female child, after a labour of about six hours. The confinement was a perfectly normal one and no instruments were used. From the moment the baby was born it cried incessantly. Having examined the infant, which seemed physically quite sound, I left the house at about 9.45 p.m. I was called out at 8 o'clock the following morning by the father, who informed me that the baby had been crying all night, and now appeared to be dying. On arrival at the house I found the child was dead.

On June 24th I performed a post-mortem examination. The baby weighed about 6½ lb. There was no evidence of external violence to be seen. When the thorax was opened the most outstanding feature was the presence of a large globular swelling on the antero-lateral aspect of the right side of the thymus gland. On further examination this swelling proved to be a cyst about as large as a walnut, which appeared to be growing downwards and backwards. Immediately behind the inferior extremity of the cyst lay the ascending aorta. A thick, glairy fluid was expelled from the tumour. The thymus gland itself was greatly enlarged, and seemed to occupy a good deal of the upper portion of the thorax. No other abnormality was discovered at the examination except for a small cyst on the upper pole of the left kidney.

As a result of these findings I concluded that death was due to syncope caused by pressure of the enlarged thymus and cyst on the aorta.

A CASE OF INTESTINAL OBSTRUCTION

The following example of intestinal obstruction of rare origin seems to merit record.

A married woman, aged 28, was admitted to the Royal Infirmary, Huddersfield, with the following history. She was quite well until two days before admission, when she commenced to have pain across the lower abdomen. This pain was continual, and, on admission to hospital, was felt more on the right side of the lower abdomen. She had no vomiting, and there was no history of bowel trouble. Micturition had been scalding for the last two weeks, but there was no frequency. Her last period was seven days before admission, and for about a year she had suffered from leucorrhoea, which was yellow and irritating.

Examination.—The abdomen was moving fairly well. Tenderness was marked in the right lower abdominal quadrant, and there was some rigidity. A tender, but not movable, mass was felt in this area. There was no abdominal distension, and nothing of importance was revealed per vaginam. It was thought that the most likely diagnosis was an appendix mass. Temperature 100°, pulse 96, respirations 22.

Operation.—A Battle incision was made, and the following were the findings. The last eight inches of the small intestine and the caecum were very enlarged and hard. The small intestine above this was only slightly distended. Under the impression that the condition was some unusual form of tuberculous caecum, because of the small bowel involvement, or perhaps one of neoplasm, an ileo-transverse colostomy was performed, and as the small intestine above the mass was not much distended and the patient's condition good, a

resection of the affected ileum with the caecum and ascending colon was performed, it being necessary to enlarge the original Battle incision to permit this (the nerves being preserved). The specimen was opened, and was found to be packed with small particles that looked like pieces of wood, about 3 by 1½ mm. The mucous membrane of the affected ileum and the caecum was extensively ulcerated, there being little normal mucous membrane left. The thickening of the wall of the bowel constituted a kind of solid oedema.

Progress.—On further questioning the patient it was discovered that she was very fond of coco-nut macaroons. It appears that she had made some of these cakes three days before admission to hospital, and had eaten the material which was left in the pot. The substance in her bowel was coco-nut. The presumption is that it had formed into a mass in her stomach and had passed to the ileo-caecal region, where it had become impacted. The patient made an uneventful recovery, leaving hospital quite fit. I am indebted to Mr. Pye-Smith for permission to publish this case.

ARTHUR H. RICHARDSON, M.B., F.R.C.S.,

Resident Surgical Officer, Huddersfield
Royal Infirmary.

LIGATURE OF EXTERNAL ILIAC ARTERY AND VEIN IN A MAN AGED 67

A man, aged 67, who had been a labourer in a gas-works and had frequently been in contact with tar, presented himself with a raised ulcerated area on the left side of the scrotum of many years' duration. Removal of the growth, with both testicles and clearance of some slightly enlarged inguinal glands, was carried out; section of the growth showed it to be an epithelioma, and section of the lymph glands showed chronic inflammatory change only.

The patient was seen eight months later. He had a swelling in the left Scarpa triangle at its upper part, there being a transmitted pulsation from the underlying femoral vessels; the lump was the size of a hen's egg, and was fairly well fixed to the deep structures. It was thought hazardous to remove the malignant gland—for such it proved to be—at once for fear of being forced to tie off the vessels *in situ* as a necessary part of the operation, and it was decided to tie off the external iliac artery and vein as a preliminary operation and remove the gland when a collateral circulation had been established.

The classical incision parallel to and above the outer part of Poupart's ligament was made and the vessels reached by stripping up the peritoneum; the vessels were tied off separately by means of a double thickness of No. 4 catgut and a lymph gland of the external iliac chain removed; this on section showed chronic inflammatory changes only. The leg was kept warm in cotton-wool, and an electric lamp put inside the protecting cradle; during the first nine days after operation there was no cause for anxiety, and it was noticed that the tumour in Scarpa's triangle was decreasing in size. On the tenth day his left leg swelled and became painful; then it was feared that gangrene might set in: it was concluded that during the nine days after operation the amount of blood delivered by the collateral arteries was exactly balanced by the amount of blood drained away by the collateral veins, and that on the tenth day there was a sudden full opening out of the collateral arteries without a corresponding dilatation of the draining veins, and the obvious remedy was raising the foot of the bed as high as possible to invoke gravity. The swelling subsided during the next twenty-four hours. The gland was removed without event a few days later, and it was found possible to dissect it from the vessels with the sole sacrifice of the internal saphenous vein; the patient made an uninterrupted recovery.

A section of the gland showed the cells to be similar in type to those of the parent growth.

Longtown, Cumberland. ROBERT RUTHERFORD, F.R.C.S.

Reviews

PREVENTIVE ASPECTS OF MEDICINE

A series of lectures conducted at King's College Hospital Medical School in 1933-4 has now been published by the *Lancet* under the above title.¹ The General Medical Council has recorded its view that throughout the whole period of medical study the attention of students should be directed to the preventive aspects of medicine, and the Committee on Medical Education of the British Medical Association says in its recently published report that "from the beginning of the curriculum, and throughout, attention should be directed primarily to health, its preservation, perfection, or restoration, and not to disease." But there is advantage also in bringing together and summing up, for the benefit of both the student and the practitioner, the present volume of knowledge about the prevention of disease and the applications of this knowledge which fall within the range of day-to-day medical practice. This is what the book under review sets out to achieve. Altogether twenty-five lecturers, each a recognized authority on a branch of medicine, contribute articles which are, in most cases, models of concision, clearness, and accuracy. Names like those of Newman, Leonard Hill, Still, Glover, Greenwood, O'Brien, Poynton, Briscoe, and Topley convey a guarantee that the facts given are reliable and the views expressed are abreast of the times. There is, of course, no attempt to cover the whole field of public health: environmental hygiene is dealt with only in so far as it touches upon the work of the general practitioner. Otherwise the book covers the range of preventive medicine as applied, from the modern point of view, to the individual's mode of living. It is well printed, light to the hand, and contains a full index.

FILTERABLE VIRUSES

It is five years now since Dr. P. HAUDUROY produced his first book on filterable viruses. It was not confined solely to filterable viruses, but considered also the question of filterable forms of bacteria; in fact, quite a considerable space was devoted to the latter subject. The rapid advance made in our knowledge of filterable viruses since 1929 convinced Dr. Hauduroy that to bring his book up to date meant rewriting it. This he has done, and the result is an entirely new book entitled *Les Ultravirus Pathogenes et Saprophytes*,² concerning itself solely with the filterable viruses. The author has done wisely to exclude the filterable forms of bacteria, for, as he rightly says, these differ obviously from the filterable viruses and require separate treatment. This is not the only improvement; the whole book strikes one as better done, better balanced. The first portion, some sixty pages in extent, is devoted to technique—a valuable addition. It is perhaps inevitable that a national or even individual outlook should pertain where technique is concerned, but there is little excuse for passing over Elford's work when dealing with ultrafiltration. The sole reference to him here concerns the sterilization of collodion filters with ultra-violet light! And the section on staining viruses is inadequate: no mention is made of the use of Giemsa's or Castaneda's stains. Still there is much sound and valuable advice in these technical chapters.

The main portion of the book is devoted to a description of the different viruses pathogenic for plants, bacteria

(bacteriophage), insects, birds, and mammals. The plant virus section is very sketchy—half a dozen pages in all. This is insufficient for a consideration of the many interesting facts which have been discovered in connexion with these plant diseases, particularly those concerning transmission. The section on bird viruses is quite comprehensive, but one is tempted to question the use of the term "parapsittacosis" for the virus of Pacheco. Apart from the fact that both this virus and psittacosis virus produce an illness in the parrot there is no resemblance, and, after all, the appearance of a sick parrot has little that is distinctive whatever the cause. The description of the mammalian viruses takes up about half the book. It is a little uneven, some sections being well done and quite adequate, others sketchy and inadequate. Trachoma, for instance, is dismissed in a dozen lines and warts in five, yet trachoma has been the subject of much interesting research, and Shope's work on papillomatosis of rabbits had given added interest to the question of warts. And the description of influenza finds no mention of the Hampstead work. Surely there was time to include this in view of its importance.

The closing chapters are of a general nature, such as the physical characters of viruses, their physiology, immunity to virus infections, their nature and origin, and the existence of saprophytic examples of this group of micro-organisms. Dr. Hauduroy is convinced that viruses are living things, and in the main his views conform closely to those held by the majority of virus workers in this country. The remarks on false invisibility strike the right note, but one is astonished to find vaccinia and herpes placed in the same size category as foot-and-mouth disease and the bacteriophage. Elford's work is completely overlooked, and Barnard's, too, for that matter, which is surprising since the author has obviously read widely in the virus literature. It is a pity, also, that the book has no index.

Although the modern textbooks of bacteriology devote a considerable space to a consideration of the filterable viruses, there is still room for a small book giving a reliable account of these agents which will serve as an introduction to the subject. Dr. R. W. FAIRBROTHER'S *Handbook of Filterable Viruses*³ is just such a book. The author has a first-hand acquaintance with his subject. What is more, he has kept an open mind on the various controversial points inevitable in a rapidly developing study such as this one, and so is well fitted to the task he has set himself. The book is confined to those filterable viruses which cause disease in man. It opens with a brief historical outline, and then passes to a consideration of the nature of these viruses. The statement in this chapter (p. 11) that "there is every indication that the viruses . . . form a very heterogeneous group" is rather sweeping, and in the section on centrifugalization it seems rather misleading to cite some of the earlier experiments on psittacosis as an example of the errors inherent in this type of experiment. It was by means of the centrifuge and with this virus that it was first shown that the virulence and other specific properties resided in the elementary bodies. Following this are chapters on cultivation and microscopy and on epidemiology and immunity, both quite good, though we do not understand why the author should still have doubts about the test-tube immunity reactions. Classification has been wisely left alone, the viruses being merely grouped under the headings accepted, probable and possible. It is under these headings in the second half of the book that the viruses known to infect man are described. No one could expect to write a book

¹ *The Preventive Aspects of Medicine. A Series of Lectures delivered at King's College Hospital Medical School. London: The Lancet Ltd. 1934. (Pp. 376. 10s. 6d. net.)*

² *Les Ultravirus Pathogenes et Saprophytes. Par Dr. Paul Hauduroy. Paris: Masson et Cie. 1934. (Pp. 462. 60 fr.)*

on this subject which would meet with general and unqualified approval, but Dr. Fairbrother has steered a very satisfactory middle course. It is the best book of its kind which has been produced, and can be strongly recommended to students of medicine who wish to know something of this important group of disease agents.

BASSINI'S OPERATION

It is just fifty years since Bassini of Padua published his method for the radical cure of an inguinal hernia, and in the next five years he operated upon 216 cases, in 200 of which the operation was a complete success. When we consider that this was a new operation of a complicated nature carried out before the days of aseptic technique, we must admit that such an achievement marked an epoch in the history of surgery. The original description of the operation was, however, lacking in detail, and its tradition is therefore far from exact. Professor CATERINA of Genoa, a pupil and assistant of Bassini, has now rectified this in a manner fully worthy of the great teacher to whom the book¹ is intended as a tribute.

The volume consists of a very clear and exact description of the operation, which is in itself of value, but its chief glory, and one which places it on an entirely new plane in surgical literature, is a series of sixteen plates illustrating in colour on their natural scale the full details of the operation. The plates have been executed by Dr. Orazio Gaigher from dissections prepared by Professor Catterina, and they entirely eclipse any productions of the kind which we have ever seen. Only a combination of high technical knowledge with supreme artistry in water-colour drawing could have produced such exquisite work. As a precise description of a particular operation the book is of real value, but as an artistic production it will be the envy of every surgeon who has ever attempted to describe his work.

An English translation has been published almost simultaneously by Messrs. H. K. Lewis at 30s.

SPINAL ANAESTHESIA

Dr. G. R. VEURS begins the preface to his volume on *Spinal Anaesthesia*² with the following sentence: "This book constitutes a survey of the experimental and clinical records in the field of spinal anaesthesia for the past forty-nine years." This statement is definitely misleading, and the reader who turns the pages for details in the administration of stovaine or percaine will receive a rude shock. Practically no mention is made of these two drugs, which are still serving a useful purpose both in this country and on the Continent. Stovaine held the field for many years, and it is surprising that no mention, except in a list of references, is made of Barker's work with heavy solutions of this drug. As a practical handbook in the use of novocain for spinal anaesthesia, however, this book has much to commend it. The author has evidently taken considerable pains to perfect his technique, and it would appear that, in his hands, spinal anaesthesia with novocain is perfectly controllable.

The opening chapters deal with the anatomy and physiology of the central nervous system, and with the characters of the cerebro-spinal fluid. Although the chemistry and physics of the fluid are dealt with no mention is made of its specific gravity—a curious omission in a work of this sort. It is also a little startling to see that one of

¹ *L'Opération de Bassini pour la Guérison Radicale de la Hernie Inguinale*. Par Docteur Attilio Catterina. Paris: Félix Alcan. 1934. (Pp. 57; 16 plates.)

² *Spinal Anaesthesia: Its Technique and Clinical Application*. By George Reuben Veurs, M.D. London: H. Kimpton. 1934. (Pp. 229; 84 figures, 21s. net.)

the functions of the cerebro-spinal fluid is to permit anaesthesia. The same might be said of the respiratory tract or the rectum. Chapters are devoted to circulation and respiration, and the effect that a spinal anaesthetic has on these two systems. The author discusses fully the action of novocain on the spinal nerves, and explains why the motor block produced is usually less in extent than the sensory block. In his own practice he claims to produce the required amount of anaesthesia, and for the requisite time, by varying the dose of novocain injected and by varying the posture of the patient after injection.

In spite of its omissions this book should provide much of interest to those who frequently employ spinal anaesthesia. It is well produced, and there are numerous illustrations and diagrams. There are also good lists of references at the end of many of the chapters.

AN IRISH MEDICAL MANUSCRIPT

The fifth fasciculus of *Irish Texts*³ is a handbook of gynaecology and midwifery translated or adapted from the *Rosa Anglica* of John of Gaddesden and from the *Trotula* of the school of Salernum. It is preceded by a treatise on the treatment of wounds, by some good counsel to the physician himself, and by a discussion on the treatment of scabies. The transcription has been made by WINIFRED WULFF, Ph.D., who has already edited an Irish translation of a part of the *Rosa Anglica*, and the fasciculus is dedicated to Dr. Singer and to Dr. Kirkpatrick. The manuscript is described as being written on vellum, richly illuminated, "and the age of the Lord when this book was made was one thousand years and three hundred years and twice twenty years and twelve years more; this book was finished in the year in which Shane Og Mac an Aithne was killed; and it was in the house of Dermot O'Meagher's son it was written." The names of the scribe and of the translator are not known. We are grateful to Dr. Wulff for the transcription, but there is still much work to be done in connexion with the manuscript, apart from the desire to know who Shane was, why he was killed, and where Dermot lived. Dr. Wulff has supplied parallel passages from the printed editions issued two hundred years after the manuscript was written, but this is not enough. A literal translation into Latin or English should be made for the convenience of those who are ignorant of the Irish language. It would then be possible to determine how far this early manuscript differs from the printed versions of the *Trotula* and *Rosa*.

DISEASES OF THE TONSIL

In *Modern Advances in Diseases of the Throat*,⁴ by Mr. ARTHUR MILLER, a compilation has been made of some literature mostly published during the last four or five years and relating almost entirely to diseases of the faucial tonsils. The author has relied mainly for his material on *Tonsil Surgery*, by Dr. Robert H. Fowler, and *Children's Tonsils In or Out*, by Dr. Kaiser, both of which excellent books were reviewed in these columns at the time of publication. He also makes use of the Semon Lecture delivered by Professor Kahler in 1932 and some articles and abstracts in the *Journal of Laryngology*.

The book might be useful to a reader quite unacquainted with recent literature, but as no attempt has been made to review recent work in the whole field of laryngology the title produces a feeling of disappointment. The last

³ *Irish Texts*. Fasciculus v. Edited by J. Frawley, P. Grosjean, and S. J. and J. G. O'Keefe. London: Street and Ward. 1934. (Pp. 101; 5s. net.)

⁴ *Modern Advances in Diseases of the Throat*. By Arthur Miller, F.R.C.S., D.L.O. London: H. K. Lewis and Co. Ltd. 1934. (Pp. xii + 129; 49 figures, 1 coloured plate. 16s. 6d. net.)

chapter, in which the author dismisses malignant disease of the tonsils and soft palate in three pages with an unconvincing advocacy of the advantages of diathermy, completes the impression of the superficial and ephemeral character of the book. The admirable way in which the publishers have produced the letterpress and reproduced the illustrations is worthy of a more serious contribution to the literature of the subject chosen.

Notes on Books

Dr. C. F. WHITE's *Aids to Sanitary Science** has reached its second edition. Much useful information is contained within its modest limits, but compression has sometimes resulted in sheer obscurity, as in the section on vital statistics. Further, the logarithmic method, so called, should be used only for the recalculation of erroneous inter-census population estimates. The article on meteorology does not refer to the Kew pattern barometer or to the millibar of pressure, though both these are now official at the Meteorological Office. It should be noted also that yellow fever is by no means eradicated from West Africa, and that *Leptospira icteroides* never was its causative organism. Such defects as the foregoing mar a book which, on the whole, is pleasantly written and quite frequently displays exemplary conciseness.

A new reference book, *The Author's and Writer's Who's Who*,⁹ has been launched by the Shaw Publishing Company, under the editorship of Mr. EDWARD MARTELL, with the assistance of an advisory committee. It is mainly intended as a guide-book for authors, editors, journalists, and publishers in all matters relating to their work. Its chief feature is a biographical directory of more than 600 pages, arranged in double columns on the plan of *Who's Who*. There is also a register of writers on specialized subjects, an index of works of reference and sources of information, and a directory of British and over-seas publications, together with much other classified information of interest and value to persons concerned with the art of writing or the business of literary production.

At a meeting of the Medical Association of South Africa, held at Johannesburg in November, 1932, Dr. A. S. BOYD read a paper on the "Treatment of Cancer by Modified Methods in Serum Therapy, with Record of Recovery in a Case of Secondary Sarcoma." This has now been published in pamphlet form, with illustrations, by Messrs. Oliver and Boyd, of Tweeddale Court, Edinburgh.

The second and final part of the *Handbook of Chemotherapy*,¹⁰ by Dr. V. FISCHL and Professor H. SCHLOSSBERGER, is concerned with metallic compounds, the first part (reviewed in these columns on August 20th, 1932) with the non-metallic compounds. The chief metals discussed in the part under review are arsenic (207 pages), mercury (75 pages), gold (51 pages), antimony (42 pages). Other metals are dealt with in less than twenty pages each. Iodine compounds are included in this volume (58 pages). In the first place the authors are to be congratulated on having provided an encyclopaedia of the science of chemotherapy in a volume of under 1,000 pages. This has been achieved by a liberal use of tables. For example, the article on arsenical derivatives occupies 204 pages, which are divided into 143 pages of print, 27 pages of tabular matter, and 34 pages of references. These figures indicate the general character of the book, which is essentially that of a work of reference. The need for such a work is best indicated by the fact that the references to the literature on organic arsenicals number nearly 3,000. It will certainly be found invaluable by

all who are interested in the subject of chemotherapy. Perusal of its pages impresses the reader forcibly with the vast amount of work that has been carried out in recent years in chemotherapy. The tables give data concerning the activity of thousands of different compounds, and it must be remembered that the published results do not indicate the total work performed, for in this subject a large proportion of negative findings are never published. The authors have provided a satisfactory guide to a mass of literature which is almost inaccessible owing to its bulk.

Preparations and Appliances

CAUTERY AND LIGHT APPARATUS IN THE OPERATING THEATRE

Dr. R. E. JOWETT (Sunderland) writes:

The apparatus described below comprises a control unit arranged for mounting on the wall. In my operating theatre this has been set in a suitable recess behind a glass panel.

The control provides a transformer, having two secondary windings for cautery and surgical light circuits respectively, each being provided with rotatory rheostats. The secondary circuits render the apparatus practically shock-proof. A voltmeter, having a scale reading from 0 to 10, is connected across the light circuit—a handy safeguard in preventing the burning out of small illuminating lamps. The considerable range necessary for bronchoscope lamps and the larger bulbs used in headlights is nevertheless available.

Leading from this control unit, cables are provided in the building to a point above the operating

NEWTON & WRIGHT LTD

table, from which point a rubber-covered multiple cable is suspended. This cable is of relatively large proportions, in order to reduce its electrical resistance to a minimum, having regard to the low voltage used in cautery work. This cable, dropping from the ceiling, is adjustable by means of a simple counterweight and pulley system, and terminates in a chromium-plated sphere fitted with two pairs of terminals for connexion of the cautery and light instruments. Cautery burners requiring current up to 30 amperes may be used.

The figure gives a good idea of the apparatus, and it will be observed that the design eliminates the use of trailing cables and "extras" near the operating table. It can be washed down, and there are no projecting parts to collect dust. The sphere is easily pushed away to give head room when working, whilst the surgeon's mobility is but little interfered with. The fitting is neat, and has proved extremely satisfactory in use.

It was made for me by Messrs. Newton and Wright Ltd., 471-3, Hornsey Road, N.19.

THE BRITISH ASSOCIATION*

PHYSIOLOGY OF VISION

Two papers in the Section of Physiology dealt with theories relating to visual sensation. Dr. F. W. Edridge-Green said that it had been proved that the cones of the retina were the percipient elements for vision, but the hypothesis that their direct stimulation by light was the essential factor had been assumed in the absence of evidence to this effect. Indeed, the assumption that the colourless and transparent cones could be so stimulated was contrary to all photo-chemical laws, since no effect could be produced by light without its being absorbed. The speaker held that stimulation of the cones was effected as the result of the photo-chemical decomposition of the liquid surrounding them, sensitized by the visual purple. The rods were not percipient elements, but controlled this visual purple. He contended that this theory explained satisfactorily every known fact of vision, including numerous ones which were inexplicable from any other standpoint.

Dr. Ivy Mackenzie pointed out that the function of the anatomical substratum of human vision might be considered from the point of view of physics and biology, as well as of physiology. Physical considerations predominated in the analysis of events in front of the retina. Psychological interpretation played a large part in the events behind the *areae striatae*, while the processes between the retinae and *areae striatae* lent themselves to anatomical and physiological observation. The visual pathways between the retinae and *areae striatae* comprised the basis of visual sensation, as distinct from perception. This neural compendium was of bilaterally symmetrical conformation, and a knowledge of its constituent parts provided the main standard of reference in the localization of brain disease. In the lower vertebrates the bilateral symmetry of this neural compendium was related to the symmetrical character of somatic movement. The tendency to right-handedness in the human subject revealed a difference between the right and left sides of the brain in respect of participation in visual reaction, but only when vision was concerned with perceptual reactions.

PSYCHOLOGY OF SOCIAL PROBLEMS

The presidential address of Dr. Shepherd Dawson in the Section of Psychology contained a strong appeal for the further investigation of the mental aspects of social welfare, which, he said, had been relatively neglected in comparison with the attention paid to the material aspects. The solution of problems such as those of supply and demand, labour and capital, law and order, hygiene, housing, and local and international rivalries, were to be found ultimately in the forces which moved men to action, in their inherited tendencies and acquired habits, in the mentalities of the groups to which they belonged, and in their relations to these groups. If opinions were to yield place to knowledge, the scientific method was just as necessary here as it was in chemistry, physics, or biology. There was a real distinction between ability and capacity; the first was actual, the second potential. Ability was measurable by what could be done here and now; capacity could usually be estimated by what could be done after a course of training. All examinations were tests of ability. Innate qualities only existed with reference to certain external conditions, and must be diagnosed and measured in relation to those conditions. Where the essential training and environmental conditions varied, inferences regarding capacity could only be made with little certainty. Psychologists had hitherto been more concerned to distinguish and measure different kinds of ability which seemed to be dependent on native capacity than to prove their innate basis. It might be possible in the future to evaluate mental characters with some approximation to the accuracy with which physical characters could be assessed. What was needed was more extensive and more operative work. The fact that on

the whole the least efficient members of the community had the largest families had caused some concern, for it suggested a dilution of the national stock-in-trade. There was, however, very little exact information about the intellect of parents, the number of children who survived to establish families of their own, and their mental status. What little there was pointed to the need of further investigation, for it suggested that the casualties were higher among dull children; but that the losses were more than made good by the greater number of births. The problem was not so serious as some had maintained, but it was sufficiently serious to make this and other problems of mental inheritance worthy of investigation. There seemed to be evidence that there was a correlation between the intelligence of parent and of child; bright parents had a higher percentage of bright children, and defective parents of defective children, but defective parents sometimes had bright children. It seemed possible that the mental deficiency of either defective or bright parents might be due either to external causes or to defective inheritance. The theories of genetic inheritance which had proved to be true in the case of plants, the lower animals, and human anatomical and physiological characters, might apply also to mental characters. If this were so, it was important that these characters should be distinguished, and the manner of their inheritance traced. This would demand the co-operation on a big scale of medical practitioners, biologists, statisticians, and teachers.

SLEEP AND HYPNOSIS

Dr. William Brown, Wilde Reader in Mental Philosophy, Oxford, delivered an address in which he compared the hypnotic state with natural sleep, citing experimental and clinical evidence. Deep-going differences had been thus revealed, as well as superficial resemblances. For example, the muscles were relaxed in sleep, but rigid in hypnosis; tendon reflexes diminished with the onset of sleep, and eventually disappeared, but were retained in all stages of hypnosis. Voluntary reactions to a prearranged stimulus or signal could be elicited in hypnosis, but not in sleep. Yet sleep could pass into hypnosis, and vice versa; there was therefore reason to recognize the existence of some close relationship between them. Moreover, mental dissociation with amnesia could occur in both conditions. Both states might be therapeutically recuperative, and both involved susceptibility to suggestion. Mediumistic trance and cataleptic stupor showed close similarities with the hypnotic state. Sleep was linked up with other manifestations of these states in the phenomenon of dreaming. Measurement of the psycho-galvanic reactions in these various states had thrown further light on their psychophysiological resemblances and differences. On the neurological side the relation of sleep to hypnosis was probably best expressed in terms of Pavlov's theory, according to which both states involved an internal inhibition in the cerebral cortex; this spread to the subcortical centres in sleep, but remained limited to the cortex in hypnosis. From the therapeutic standpoint hypnosis had proved useful in some cases of war neurosis, in the recall of forgotten emotional upsets which were giving rise to such phenomena as somnambulism, and in the adjusting of disturbances referable to the deeper levels of nerve function.

Mr. W. Whately Carington described an investigation in which word association tests had been applied to three mediums in their normal states and to five trance personalities associated with them. In one case a clear-cut difference between the normal and trance personalities had been thus disclosed. In the second an equally unmistakable similarity had been found. In the third, where four personalities were involved, a complex system of relationships had been discovered. The classical view of secondary personalities, he pointed out, would anticipate significantly similar sets of reactions (determined by the common subconscious) in cases where the trance was genuine, so that no wilting misdirection occurred, and suggested that even the latter would not escape detection by the psycho-galvanic reflex. It was accordingly rather difficult to reconcile the results thus obtained with current theory.

* Continued from page 527.

VOCATIONAL GUIDANCE

The methods and results of vocational guidance were discussed by various readers of papers in the Section of Psychology. Miss J. A. Wales, who described the current methods in Berlin, outlined the arrangement for the giving of trade talks by the Ministry of Labour's vocational advisers to children who were about to leave school. She explained the organization of the juvenile departments of the employment of labour exchanges, where individual advice was given. Cases of difficulty were referred to the special medical officer if the difficulty was one of health, or to the psychological department if there was any doubt as to vocational aptitude. The results of a vocational guidance experiment in Fife were also reported. A group of 472 children attending urban and rural schools had been examined; their ages were between 11 and 12, and psychological re-examinations had followed at approximately yearly periods during the subsequent school attendance. The town children proved to be on the whole superior to the country children in abstract tests, but inferior in practical tests. The verbal tests were found to have the highest consistency in the age period under review. The follow-up studies yielded tentative estimates of the minimal qualifications necessary for various kinds of work. Mr. C. A. Oakley described a recent survey made of all the vocations which school children were likely to take up, from accountancy to wholesale selling, with a view to assisting vocational advisers in schools in dealing with normal cases. He announced that an occupational survey had been prepared, which included information about the necessary abilities and other qualities. Another survey had been made with the intention of determining what psychological tests for children over the age of 11 were at present being used in Great Britain. Mr. A. Rodger described the results of an examination by the National Institute of Industrial Psychology of 400 new Borsal boys. Of those who were subsequently put into work-parties judged suitable for them by the institute, 69.5 per cent. had proved successful. Of the control group in which the Borsal house-masters had been the sole judges, 45.6 per cent. had proved successful. He regarded this difference as statistically significant. He added that a survey of the "failures" of the National Institute showed clearly the importance of the part which should be played in vocational guidance by the study of temperament. Dr. D. B. Cattell maintained that the psychologist ought to be an integral member of the local education service. His main value was as a psychotherapist, treating difficult, neurotic, and delinquent children, who were far more numerous and much more neglected than was generally supposed. He was also needed to grade normal children, and to select defective children and those with special educational disabilities. He should design schemes of guidance, and advise on matters relating to the curriculum and school organization. A nucleus of teachers should be trained in routine mental testing.

VITAMIN C

A discussion was held in the Section of Chemistry on ascorbic acid (vitamin C). The history of the subject was narrated by Professor A. Harden, who traced the steps by which the strongly reducing hexuronic acid found in the suprarenal glands and in many vegetable juices had been shown to have powerful antiscorbutic properties. The easy preparation of this substance in quantity from paprika had provided material for the determination of its constitution, its synthesis, and the demonstration of its full antiscorbutic potency. Professor A. Szent-Györgyi said that this acid had become available for medicine too recently to permit full appreciation of its medical applications, but the preliminary clinical investigation had revealed some very striking and unexpected effects. It seemed to be able to cure several diseases against which medicine had hitherto striven in vain, such as purpura haemorrhagica, Werlhoff's disease, certain forms of haemorrhagic nephritis, haemophilia, and

pyorrhoea. Such curative effects suggested that humanity was suffering much more gravely from lack of vitamin C than had been realized previously. The major part of pathological pigmentations could be made to disappear by its exhibition. In the short space of time of two years the mysterious vitamin C had been identified, its chemical structure determined, and its synthesis effected. This unparalleled advance had been entirely due to the closest and most friendly international co-operation.

Cows' MILK

The Sections of Chemistry and Agriculture held a joint discussion on the chemistry of milk. Dr. J. F. Tocher stated that the proportions of the constituents of milk varied widely from sample to sample even in the case of bulked milk. In respect of fat and solids-not-fat percentages it had been shown that many cases occurred where the values fell below the prescribed limits under the regulations; these had been made at a time when no accurate knowledge existed of the observed minimum limits in the case of herds. The speaker remarked that this was an illustration of the importance of legal enactments following scientific knowledge, and not preceding it. One of the difficulties encountered was the method of detecting watering, and many cases had occurred when genuine milk had been erroneously condemned as having been watered. An equation had now been found by the speaker from which it was possible to detect watering within certain limits; this could be used in conjunction with the observation of the freezing point. The equation gave the relationship of the four chief constituents to the total solids other than butter fat. The predicted solids had been found to approximate closely to the actual solids in samples from individual cows. When, however, a sample was watered, the predicted values differed significantly from the actual values. Dr. Tocher considered that milk should not be condemned on the results of freezing-point determinations alone. There was as yet no standard for the freezing point of milk, and analysts were not agreed as to the nearest approach to the freezing point of water which occurred in genuine samples of milk. Dr. W. L. Davies produced a table showing the expected levels of composition of normal cows' milk and of milk which must be considered abnormal. There was evidence that abnormality was due to inefficiency in the secretory process in the elaboration of casein from the nitrogenous compounds of the blood and in secreting glucose. Abnormality in the buffer value in the acid range, in the balance of acidic and basic constituents, in the distribution of ionic and non-ionic metallic radicals (calcium), in the amounts of the various forms of casein present, and in the amount of heat-coagulable protein, was reflected by abnormality in rennet action, in "curd tension," and in heat stability at temperatures above 100° C. Dr. S. K. Kon said that biological tests had demonstrated marked seasonal variations in the total vitamin A activity and the vitamin D content of milk. Physical measurements had shown a similar fluctuation in the carotene content. The contents of the three forms of vitamin B appeared to be constant throughout the year, not being affected by the seasons. Vitamin C in milk was either rapidly destroyed by visible light or else it underwent reversible oxidation, the product reacting no more with the vitamin C reagent. The loss in activity of vitamin D was more marked in autumn and winter butters.

The association of members of the Chartered Society of Massage and Medical Gymnastics in private practice has issued a revised edition, dated August, 1934, of its *Directory*. Every person mentioned therein is qualified in massage and is registered with the society. Many hold additional qualifications, which are indicated by abbreviations. All the members have adopted an ethical code which pledges them to work only under the direction of registered medical practitioners. A copy of the *Directory* will be sent, post free, to any doctor on application to the honorary secretary, P.P.A., "Hygeia," Falmouth, Cornwall.

British Medical Journal

SATURDAY, SEPTEMBER 22nd, 1934

INSURANCE AND PUBLIC HEALTH

One of the most cogent and important criticisms of national health insurance systems is to be found in the *Canadian Public Health Journal* for July of this year. The article is not by a member of the medical profession, but comes from an eminent consulting actuary, Mr. Hugh H. Wolfenden of Toronto. It embodies an address given in that city in May, 1934, at a conference of the Canadian Public Health Association, the Ontario Health Officers' Association, and the Ontario Medical Association. The subject is admirably presented and the article very well written. It does not deal with any detailed features of national health insurance schemes or even with the actuarial problems which arise in connexion with them, but proceeds, after a brief review of the early history of insurance data and the relations between actuaries and medical officers of health, to re-examine briefly the whole problem which such schemes are designed to meet, without preconceived notions of what the best solution may ultimately prove to be.

In the course of his remarkably clear and ordered discussion the author brings out two points of fundamental importance which have been almost universally ignored or slurred over in conferences and writings on this subject. One of these is the way in which existing national health insurance schemes depart from strict conformity with the principle of insurance; the other is the appropriate position of health insurance in any comprehensive public health programme. Neither of these matters has, of course, been entirely outside the vision of some of those who in this country were responsible for initiating national health insurance, or of some of those whose business it has been to administer it; but they have not previously been enunciated so succinctly and definitely as in Mr. Wolfenden's article. In the space at his disposal the author is unable to consider them fully or to discuss whatever justification may be alleged for the unusual features to which attention is drawn. It may be wise, therefore, to emphasize that further elucidation and elaboration of these points would be valuable.

"A true insurance plan implies simply the co-operative association of a large number of individuals, who agree to share amongst themselves the burdens arising from the occurrence of a particular contingency (in this case sickness) by payment of the necessary contributions into a common fund; and it is fundamental that the group of persons must be reasonably homogeneous, that the risks must be predictable within certain obviously narrow limits, and that the claims must be absolutely provable."

With voluntary insurance funds the ultimate responsibility is the concern always of the members themselves.

and cannot be shifted on to other persons or the State. With compulsory national health insurance schemes as so far established, though the real insurance principle of shifting the burden from the individual to a homogeneous group of his own fellow members is not ignored, it is vitiated and overborne by the fact that this is not done without external aid. Indeed, the main feature of the schemes is a transference of a large part of the burden from those of the limited class included within the scheme on to other shoulders—those of the employers and the tax-payers. This feature being so prominent there comes into force the inevitable tendency to exploit the other man's ability to pay, and sometimes to prolong sickness through the continuance of which benefits may be obtained. All this is obviously true, and should be clearly envisaged. Yet it may still be worth while for the State—that is, the community in general—to establish and support such a system, and knowingly to carry some of the load and to compel employers to take their share, even while recognizing its drawbacks and imposing conditions and regulations with a view to minimizing these as far as may be. Whether this is worth while, and, if so, in what proportions the burdens should be distributed, is not in the least a medical question, but must be determined by each State in the light of its own economic, social, and political conditions. At present, however, some such system appears to be an almost essential feature of the social economy of Western civilization on its existing basis.

Further, unless illness is to be regarded as being either a mysterious dispensation of providence or a quite unavoidable accident, it is contended that the establishment of any national health insurance system which removes the main financial obligations of illness from one section of the community to the rest should logically be preceded, or at least accompanied, by extensive health propaganda, by the enforcement of public health measures by penalties for their breach, and by the requirement of compulsory periodic health examinations of every individual, as well as the comprehensive registration of sickness. These are looked upon as essential measures of control, without which the insurance scheme must be inequitable to the insured and unjust to the uninsured portion of the community. "We are permitting people to become ill individually through misfortune or ignorance or carelessness, but when they have succeeded in becoming ill it is then said to be the responsibility of the whole community to cure them." It may be true that in a comprehensive review of preventive health measures *de novo* it would be "much more logical to consider the establishment of health insurance to alleviate the economic burdens of the residual sickness which the public health programme would be unable to prevent"; and that "health insurance in such circumstances would cost far less than under present conditions and would be far easier to control." It must be remembered, however, that, after all, in a very large number of cases illness is a sheer misfortune and that very few sufferers

really enjoy it ; that in a further proportion it is the community rather than the individual who is at fault ; and that, as a matter of practice, it would almost always be impossible to prove that a particular illness had been brought about exclusively by the patient's own wilfulness or carelessness.

The place of the English insurance scheme among preventive health measures was not ignored by its promoters, although, apart from a small amount of health propaganda undertaken by some insurance committees and the much more important preventive work done by insurance medical practitioners in their daily consultations, full advantage has never been taken of the opportunities afforded. More measures of control may be needed, and the relative advantages and disadvantages of compulsory periodic health examinations and of the systematic and confidential registration of illness, or of some particular forms of illness, might well be further considered. Towards the conclusion of his article Mr. Wolfenden points out that, whatever form of insurance is adopted or whatever are the conditions in which it is established, the fullest co-operation between the public health officers, the medical and dental professions, and the actuary would still be required.

PROBLEMS OF SOCIAL PSYCHOLOGY

The presidential address by Dr. Shepherd Dawson to the Section of Psychology at the recent meeting of the British Association was mainly concerned with the assessment of natural capacity, particularly with the problems of differentiating its biological determinants from those which depended on external conditions. The President made a useful distinction between ability and capacity. The former is the resultant of innate processes and the totality of post-natal experiences summed up in the term "environment" or "nurture" ; the latter, a kind of Kantian noumenon, is a quality or complex of qualities the reality of which can only be inferred from the knowledge or skill through which it finds its expression. Mental tests, however scrupulously devised, are primarily measures of ability ; it is only when the innate qualities determining ability are unaffected or hardly affected by training that such tests also gauge capacity. To the psychologist the distinction is important in so far as it safeguards him from the error of considering the individual in a social vacuum—that is, without reference to the kind of society he lives in and the influences and incentives to which he is subjected. It does not, of course, follow that in a society which enjoyed (according to the adherents of one political philosophy) or endured (according to those who hold the opposite views) a condition of economic equality the differences between one man and the next would only be those which were genetically determined and thus a measure of relative biological worth. Even within the same family, as Dr. Dawson pointed out, there occur environmental vicissitudes which may affect the

ultimate qualities of its members. Parents, for instance, "become more experienced, or more indulgent, in the management of their children ; school-fellows vary ; and the children themselves vary in their relationships to one another and to the rest of the world."

The problems of the social psychologist are immensely complicated by our living in communities of which all the members do not start at scratch, and there could be no dissent from Dr. Dawson's view that the most humane method of overcoming this difficulty would be "to improve the conditions of life so as to give all a chance." Even then there would remain the difficulty of isolating and defining mental characteristics. As an instance of this problem, Dr. Dawson cited the confusion that has been created by the manifold definitions of mental defectiveness. According to the law, the feeble-minded are "persons in whose case there exists from birth or from an early age mental defectiveness so pronounced that they require care, supervision, and control" ; but this description merely relates an undefined psychological state to equally undefined external circumstances. Ability to look after oneself and one's affairs without supervision obviously depends in large measure upon the nature of those affairs, and thus upon the social and physical environment—a proposition which leads to the curious conclusion that a man may be feeble-minded in one environment and not in another. Dr. Dawson makes the ingenious suggestion that the increase in the incidence of defectiveness which has been attributed to a disadvantageous differential birth rate may in fact be due to the increasing complexities of civilized life, which make excessive demands on intellects that could have coped satisfactorily with the simpler conditions of, say, fifty years ago. The psychological definition of mental deficiency is hardly more satisfactory. It is based on a statistical convention that places the borderline of normality between the mental ratios of 60 and 80. But this apparent exactitude may be misleading, first, because none of the mental tests in regular use can differentiate ability from capacity with complete certainty, and, secondly, because, as Dr. Dawson pointed out, feeble-mindedness may be due to a variety of genetic factors, and among its forms there may be some which are not distinguishable at all by means of intelligence ratios.

Genetical studies on the inheritance of ability and defectiveness have occasionally yielded useful information, but in many of them too much reliance "has been placed on rough-and-ready estimates based largely on social and professional success." One of the most carefully controlled studies in this class—*An Investigation into the Relation between Intelligence and Inheritance*,¹ by Dr. Evelyn M. Lawrence—supported the opinion that intelligence is hereditary and more abundant in the higher than in the lower social levels, but only with very material qualifications. In the first place, the difference between the classes, in circum-

¹ Cambridge University Press, 1931.

stances of equal environmental opportunity, did not appear to be very great, and in the second, the large number of low intelligences in the investigator's highest class, and the even more striking list of brilliant children in the two lowest classes, showed the hazardousness of generalizations about social classes as such. Dr. Dawson sums up the matter in the statement that the best-founded studies into the inheritance of intellect have shown "that bright parents have a higher proportion of bright children and that defective parents have a bigger proportion of defective children than do normal parents, but they have also shown that normal, even brilliant parents sometimes have defective children, that defective parents sometimes have normal children, and they suggest that the mental deficiency of children of either bright or dull parents may be due either to external causes or to defective inheritance. The main facts have probably been made out, but the details are lacking, and will not be available until exact measurements have been made of the mental traits of parents and their children under conditions in which social opportunities and encouragements are equal for all." His final conclusion, that the search for unitary mental traits "will demand the co-operation on a big scale, not only of psychologists, but also of biologists, statisticians, teachers, medical men, and others," gives a just indication of the immensity of the difficulties that must be overcome before the genetics of intellect are placed on a sound scientific footing.

THE CORONARY ARTERIES IN RHEUMATIC FEVER

Acute inflammatory changes have in the past been described as occurring in the coronary arteries, and involving all their coats, in a variety of general infections, including typhoid fever, diphtheria, influenza, scarlet fever, and septic and pyaemic diseases. Similarly, these diseases may produce degenerative changes in the vessels, but their connexion with arteriosclerosis or atheroma is not clear. Rheumatic fever is another infectious disease capable of producing arterial lesions, and the manner and frequency of these changes has been investigated recently by H. T. Karsner and F. Bayless.¹ They summarize the findings of other workers on the histological changes in the coronaries in rheumatic fever, and briefly consider the relation of these changes to myocardial damage, arteriosclerosis, and cardiac pain and arrhythmias, and then give the results of their examination of fifty-six hearts that showed typical rheumatic inflammation. Of the fifty-six cases investigated there was a history of rheumatic fever in forty-seven and of chorea in one—probably a higher proportion than one might get in this country from any large series of patients with rheumatic heart disease. The ages of the patients ranged from 2½ to 67 years, and sections of the coronaries revealed in all cases oedema and fibrinoid (an intensely acidophilic substance arranged in fibrillar fashion and found most often in the media), while in the majority there were chromotropic change and alterations in the elastica; necrosis was found with a

frequency which increased as age advanced. Fibrinoid is said to be present in only a few other conditions, all of which may be of allergic origin. Infiltration of mononuclear cells and Aschoff bodies was a common finding in the adventitia, as was fibrosis in all coats of the vessels. Most of these changes were also observed in the controls, but these differed in certain respects: chromotropic change was not found, fibrinoid was inconstant, and there were differences in the elastic tissue changes and the cell infiltrations. It was concluded that thrombosis in the coronaries is not more frequent in acute rheumatism than in other severe infections. Intimal fibrosis, especially affecting the smaller arteries, was much commoner in the young rheumatic patients than in controls of the same age groups, and the authors consider that this change is responsible for the muscle damage of rheumatic heart disease rather than a primary injury to the muscle itself; in other words, it is better considered as the result of ischaemia than as a myocarditis. They believe that these arterial lesions undergo a sequence of inflammatory reactions analogous to those of the valves, and that these changes result in correspondingly severe effects upon the muscle. On the clinical side the authors consider that these pathological changes may explain the precordial pain which is sometimes a symptom in rheumatic carditis. Pain of anginal type is, however, very rare, apart from aortic incompetence; but on a few occasions thrombosis of a large coronary has been reported as occurring in young subjects with rheumatic hearts. The salient point which emerges from this investigation is, from the clinician's point of view, the suggestion that the muscle failure which ultimately supervenes in most cases of rheumatic carditis is due essentially to lesions in the coronary arteries. Formerly, increased mechanical load imposed by valve lesions, and less often by adherent pericardium, was thought to be the important factor in leading to failure in rheumatic heart disease, but it is now generally believed that a healthy heart muscle will stand up to an abnormally heavy burden—for example, in coarctation of the aorta—for very long periods of time. On this view the rheumatic heart with valve disease fails chiefly because of impaired muscle, and only a secondary part is played by the valvular lesion; but according to the conception of Karsner and Bayless this muscle impairment is not a direct one, and results chiefly from an ischaemia.

UNDERNOURISHMENT AND UNEMPLOYMENT

The Children's Minimum Campaign Committee is publishing this week a further statement, *Evidence on Malnutrition*, by way of supplement to the memorandum on *The Scale of Needs*, which was submitted to the Unemployment Assistance Board on behalf of the committee by its chairman, Miss Eleanor Rathbone, M.P., in July last.² The earlier memorandum urged that the scales on which unemployment allowances are to be granted should be based on scientifically determined estimates of the expenditure needed to satisfy the requirements of healthy living. The present statement gives expression to "a widespread feeling, especially among those whose work brings them into direct contact with the children of the working classes

¹ *Amer. Heart Journ.*, June, 1934, p. 557.

² *British Medical Journal*, August 18th, 1934, p. 311.

in their homes or in the schools, that there exists to-day far more undernourishment than the official reports suggest." A number of considerations are put forward, each of which, in the committee's belief, contributes to the apparent discrepancy between the official figures of malnutrition among elementary school children and the "acknowledged fact that large numbers of these children come from homes where, after rent is paid, the income cannot possibly admit an expenditure on food and clothing which is adequate according to any authoritative scale." The general trend of the pamphlet may be gathered from the first four side-headings: "Absence of a satisfactory standard"; "The standards adopted may be too low"; "Effects of underfeeding may be delayed"; "The condition of the unemployed masked by improved general conditions." The great importance of adequate and proper food in the first five years of a child's life is discussed in relation to the general problem, followed by reference to two mitigating factors—the self-sacrifice of parents and the provision of school meals and milk by local education authorities. A point stressed is the difficulty of determining the early signs of malnutrition. "The inadequate provision made by many local authorities and the limitations of the medical test, which may only discover damage when it is too late to repair it, make it impossible to regard school meals as a reliable corrective for an inadequate income in the home." Lastly, the committee gives its reasons for believing that unwise expenditure by poor mothers as a cause of undernourishment is much exaggerated. The pamphlet ends with extracts from medical officers' reports which give some support to the committee's arguments. Copies (price 4d.) may be had from Miss Marjorie E. Green at Room 116, Thames House, Millbank, S.W.1.

THE QUINTUPLETS

In an age when records are being broken in almost every sphere of human activity it is pleasing to find that not even feats of reproduction escape public notice. In the early hours of May 28th this year Mrs. Elzire Dionne, a young French Canadian living in a settlement two hundred miles north of Lake Ontario, gave birth to five living girls, who at the time of writing are believed to be alive and well, and for whom an English newspaper has already coined the term "The Quins." The *Journal of the American Medical Association* devotes more than three pages in its issue of September 1st to a first-hand account of this astonishing event, contributed by Dr. A. R. Dafoe, who, though he arrived after the birth of two of the infants, was present during the delivery of the remaining three. Dr. Dafoe's narrative reads like a fairy tale. With simplicity, humour, vividness, a charming modesty, and a directness of style which many might envy, he describes the acute confusion into which he was plunged on arrival at the Dionne home, the extremely efficient way in which he met the situation, and the epic struggles that were made to keep the infants alive—on May 29th their total weight was but 13 lb. 6 oz. He found the sole preparations for the confinement consisted of a tea-kettle boiling on the stove; "the father had disappeared" (later on in his account there occurs the phrase "the husband was still missing"); he was

still sleepy from a previous obstetric case that night; and the whole situation struck him as "unreal and dream-like." The delivery over, the story continues with the separate baptism of the five children; the collapse of the mother, which resulted in his having to leave the midwife with her hand on the fundus while he hurried off on a five-mile journey to get the priest; the mother's recovery; the relays of heated blankets to wrap round the babies; the scientifically tragic loss of the placenta; and the gradual restoration of order out of chaos. Later he describes how they overcame the problems of feeding and the subsequent organization required for the six patients. Dr. Dafoe's article gives a graphic picture of the rugged and virile French-Canadian settlers in his district of 400 square miles, with their sturdy, simple, and law-abiding attitude to life, their hard working days lumbering in the winter, farming, road-mending, and working in saw-mills in the summer, and he also conveys a good idea of some of the difficulties in a practice where at certain times of the year the outlying areas are reached only with difficulty by sleigh. In a comment with which he concludes his notes occurs the artless statement:

"The publicity in connexion with this case has been a serious problem, and has caused me considerable trouble and worry. There has been no let-up from the moment of the uncle's naïve inquiry to the North Bay paper as to how much it would cost to insert a birth notice for five babies born at one time. At first I resented what I felt was an intrusion into my private and professional affairs. Then I came to realize that I had no right to object to what had become a matter of Continent-wide interest."

So ends a vivid and intensely interesting account of this incredible affair. It is perhaps not an improbable prediction that somewhere about 1950 an immense fortune awaits the "Quins" when they make their *début* in cabaret or music-hall. One can, in fact, without difficulty imagine that the more enterprising showmen are at this very moment falling over each other in an attempt to secure a life-contract for what—to borrow Dr. Dafoe's epithet—may prove to be a Continent-wide "draw." But whatever their future careers may show, we can join in his wish that the babies "will continue to thrive and will be a credit to their family and to their country."

THE DENTAL SURGEON'S PLACE IN A GENERAL HOSPITAL

Recent correspondence, a paper by Mr. Harold Round, and an editorial in the *British Dental Journal* indicate considerable dissatisfaction by the dental profession with the status of the dentist on the staff of the general hospitals. Writing from Birmingham Mr. Round tells how, after an interval of thirty years, he was appointed dentist to the Queen's Hospital, and how, step by step, he attained his ideal of a self-contained unit with beds and a resident dental house-surgeon. But he had to prove his worth, and the *British Dental Journal* calls him "the happy warrior," and reviews the position held by the dentist in the large general hospitals of this country. In some the dental department is an important element in the hospital economy; in others the dental surgeon, while in theory on a level with the

honorary staff, does in fact occupy a subordinate place. Other specialisms, our contemporary remarks, have had the same fight—and have won handsomely. Dentistry lags behind, and in seeking to account for this the journal suggests that lack of a full medical education and the reluctance of other members of the staff to give up beds are not inconsiderable factors. As regards the first point the suggestion is made that candidates holding the higher dental diplomas may answer it—though it may be legitimately asked whether these higher diplomas provide very much more of a medical education than the ordinary L.D.S.—while the second can only be answered when the general staff and the managing committee appreciate the full value and needs of a dental department. At present, say Mr. Round and the *British Dental Journal*, the dentist must prove his worth before status or accommodation is accorded him. This, we think, is quite wrong. Exactly the opposite should obtain. Status and accommodation should be there, ready for the suitable man. The value of dentistry to medicine brooks no denial; in many cases it is the only cure. Probably, in the medical mind, there will always be a swing of the pendulum between the point where every tooth is regarded as providing an "overload" of infection and the other extreme where dental sepsis is of no account; but in the ordinary practice of a general hospital there must always be a large number of cases in which the value of dental treatment is beyond doubt, and those who provide this treatment should be given the same status and facilities as other members of the staff. It should further be remembered that in addition to very considerable medical knowledge the dentist must possess mechanical skill of no mean order to deal with cases such as fracture, replacement of lost parts, radium applicators, etc. That the dentist should still be doubtful of his status seems to us to indicate that many medical men pay but lip service to the much-talked-of co-operation between dentist and doctor. We hesitate to suggest that they are ignorant of the pathology of dental diseases, but we strongly urge that only in a well-found dental department can the medical student hope to acquire the knowledge that will enable him to diagnose and assess at their disease value the dental conditions which he is bound to encounter in vast numbers in his life's work. And those from whom he gets his instruction should be under no stigma of inferiority.

CAUSATION OF SKELETAL MUSCLE PAIN

It is now generally accepted that ischaemia is the cause of muscular pain, such as occurs in angina pectoris and intermittent claudication, but the immediately responsible factors remain obscure. S. Perlow, P. Markle, and L. N. Katz¹ have conducted experiments on human subjects with a view to determining the underlying factors. They found that the immediate cause of continuous muscular pain, such as occurred when an ischaemic muscle was exercised, was not produced by a single mechanism, but that muscular activity, anoxaemia, circulatory stasis, and possibly other processes contributed to its production. Various degrees of generalized anoxaemias were induced in these subjects by letting the subject breathe from a spirometer containing various mixtures of gases

at different times. Arm-clenching and leg-moving exercises were performed, complete ischaemia being brought about by inflating a sphygmomanometer cuff to a pressure considerably above the systolic. Circulatory stasis without complete ischaemia was produced by maintaining a pressure of 80 mm. of mercury in the cuff. The obstruction to the venous outflow led to the accumulation of blood in the limb. The observations consisted primarily in determining the time and circumstances in which continuous pain, as described by Lewis, Pickering, and Rothschild, developed, and the time and conditions under which it disappeared. It was found that exercise with circulatory stasis, but without anoxaemia, failed to produce pain in ten minutes in exercising leg muscles. Pain caused by exercise of both the arm and the leg during complete ischaemia disappeared after a short lag whenever the complete ischaemia was relieved, even if the exercise was continued and circulatory stasis was maintained. It seemed, therefore, that anoxaemia must be severe to become an important element in the production of pain in an exercising muscle during ischaemia. In the experiments, however, general anoxaemia failed to produce pain in ten minutes in the exercising muscles of the leg unless associated with circulatory stasis, extension of the foot being the exercise used. Stasis and anoxaemia were also found to be important in delaying the abatement of pain, even after the exercise had ceased. The authors hold that the pain-producing factor is a chemical substance which is formed during muscular metabolism and continues even while the muscle is at rest, though slowly. It was clearly possible to define a pre-pain stage, when the pain-producing substance was above normal but below the pain-producing threshold. Absence of pain, it is added, does not imply restoration of the muscle to normal.

NATIONAL INSTITUTE FOR THE DEAF

The development of the National Institute for the Deaf, since its reconstitution ten years ago, has been so rapid that the committee has been compelled to provide more commodious premises for its still expanding work. A fine freehold house, 105, Gower Street, London, W.1, has been secured, and the work of the institute will shortly be transferred thereto from the present offices, 2, Bloomsbury Street, W.C.1. The new premises and the necessary alterations and furnishing will cost approximately £12,000, and for this sum Lord Charnwood and other influential friends are now appealing to those of the public who sympathize with deafness and who desire sufferers from it to be suitably advised and helped. The committee has received some £2,500 of the amount required. A permanent centre of information and advice on deafness and the deaf is a national necessity, and, great as have been the achievements of the Institute in the past, there is no doubt that when it has the advantage of adequate and permanent accommodation its work will be of greater assistance to that large section of humanity whose ears are more or less closed to sound.

We regret to announce the death, at Stockholm, of Mr. W. H. Trethowan, F.R.C.S., orthopaedic surgeon to Guy's Hospital and surgeon to the Royal National Orthopaedic Hospital.

Globa et Vetera

THE HAMPSHIRE BOUNDARY IN THE VICINITY OF BOURNEMOUTH

Whilst those members of the British Medical Association who attended the Annual Meeting this year still have vividly in mind the geography of Bournemouth and the exceedingly interesting *Book of Bournemouth*, edited by the President and presented to us all by the generosity of the Borough Council, it may be useful to amplify slightly the references in Mr. Riddle's admirable historical sketch of the development of the town in early days. Refuting a common notion that the name Bournemouth is a modern innovation, he quotes a State Paper of 1574 which alludes to "Bournemouth, within the Hundred of Westover, adwynyng to Dorsetshire." If "adwynyng" means "adjoining," it would seem that Bournemouth was regarded as in Hampshire; if it means "adhering," then Dorsetshire claimed the honour. Or again, if someone could explain for us what the Hundred of Westover was, the problem might be solved; but the various ancient maps which I possess do not show the Hundred of Westover at all—they all concur in extending the Hundred of Christchurch right up to the county boundary on the Hampshire side, and the Hundred of Cogdeans on the Dorsetshire side; Camden gives a list of the Hundreds of Hampshire in which Westover is not mentioned. However, Westover Road is very much in evidence in the Bournemouth of to-day, so presumably Westover had a definite existence, whether or not it was recognized as a Hundred.

Mr. Riddle goes on to explain that "Burnemouthe" is shown on a MS. map of Dorset, now in the British Museum, as belonging to that county (in 1575), and says that Tresswell's map of 1586 and the map published with the 1610 edition of Camden's *Britannia* both place the Bourne stream wholly within the county of Dorset. I have not seen Tresswell's map, but I possess the map (by Kip) from the 1610 *Britannia*, and I interpret the cartographer as meaning that the Bourne is, near the sea, the actual boundary between the two counties, not that it is wholly in Dorsetshire. Saxton's map of Hampshire (1575) rather neglects this corner of the county, but it does show an unnamed stream (presumably the Bourne) definitely in Dorsetshire. According to Overton (1600) and Morden (1690), says Mr. Riddle, the stream was taken as the intercounty frontier.

Saxton's surveys were the earliest attempts at the large-scale cartography of England, and for some generations after his time publishers copied him freely; but they did extend his researches on their own account to some degree, and it is interesting to compare the various early delineations of the triangle of land enclosed between the sea front, the county boundary, and the River Stour. John Speed, for instance, in 1610 shows "Bascomb Copperas House" about two-fifths of the distance from "Allom House" (which is placed just on the Hampshire side of the boundary) to Hengistbury Head: copperas, if I remember rightly, is sulphate of iron, and allom is no doubt sulphate of aluminium. Due north of Allom House, and likewise just in Hampshire, a hamlet named Heath is shown; Iforde is duly, and fairly correctly, sited, and so is Holmhurst (now Holdenhurst). Longham is placed on the Dorsetshire side of the line and is thus spelt: in the Camden map of 1610 (itself a reprint of the original of 1607) it is also on the Dorset side, spelt Langham. Both show Perley well inside Hampshire, spelt Parlieu in Speed and Palieu in Camden; but oddly enough both authorities in their Dorsetshire maps place it in the identical situation but spell it in the modern way. Another anomaly shared by both these atlases is that they correctly place Preston in Dorsetshire in their maps of that county, but incorrectly include it in Hampshire when mapping the latter. These strange and identical blunders probably imply that they both copied some earlier authority (not Saxton, by the way); yet in some particulars they vary from each other noticeably. Thus Camden's mapmaker (John Norden in the

case of Hampshire) gives Allom Copperas House, compared with Allom House in Speed, and he spells Boscombe "Boscambe," which is nearer to the modern spelling than Speed's version. He shows Burne mouth as two separate words (on the Dorset map in this case); between that place and Parkston he places "The mynes," presumably the iron deposits, or else the alum workings, which Speed also shows.

The great Amsterdam firm of the Blaeus evidently trusted to the English cartographers for this corner of Hampshire. They copy Speed with exactness, spelling Perley "Parlieu" as he does; placing Allom House just on the Hants side of the border, with Heath due north of it; and Preston also on the wrong side of the county line. Whether the Blaeus sited Preston properly on their Dorsetshire map—as Speed and Norden did—I am unable to say, as I have only their Hampshire map before me. It is, however, clear that they copied Speed, not Norden. Thus, they follow Speed in regard to Iford, which Norden calls Iverbridge—Iver being, no doubt, a phonetic spelling of Iford. They also place Heath in the exact position that Speed does, whereas Saxton and Norden omit it altogether. Is this hamlet, I wonder, the district now called Highmoor?

I ought to add that, as those who have read the *Book of Bournemouth* know, the whole town is nowadays in Hampshire; but at what date the boundary was redrawn I am unable to say, and Mr. Riddle does not tell us, though I feel quite sure that he knows. H. R.

England and Wales

Bequest to Oxford University

A large sum of money—£30,000—has been left by Mrs. Mary Jane Williams of Witley, Surrey, to the Chancellor, masters, and scholars of the University of Oxford, to be expended in the promotion of Oxford medical education. The benefactress, who was the widow of Charles Theodore Williams, M.D., F.R.C.P., consulting physician to the Brompton Hospital, died on July 24th. Her husband died in 1912. A further £5,000 is left to the Royal College of Physicians of London, to be devoted to the exercise of hospitality and to the maintenance of the dignity of the College. Other legatees are the Master and Fellows of Pembroke College, Oxford, "in token of my husband's great affection for and desire to assist the college, of which he was an honorary fellow, to found fellowships and scholarships, or for building or endowments, or in other ways to promote the prosperity of the college which was dear to him." Sums of £100 each are bequeathed to the London Society for Women's Service, to the Medical Society of London, and to the Royal Meteorological Society. An Oxford correspondent writes: Pembroke College—originally Broadgates Hall—was founded in 1624 by James I. Dr. Thomas Clayton, Regius Professor of Medicine, was the last Principal of Broadgates Hall and became Pembroke's first Master. The college still preserves some relics of Samuel Johnson, who entered it in 1728.

Institute of Medical Psychology

Post-graduate courses in psychotherapeutic theory and method for members of the medical profession will begin on October 1st at the Institute of Medical Psychology (the Tavistock Clinic). During the first five weeks there will be ten introductory lectures, after which the main course, covering a year's work, will be arranged to suit alternate groups of those aiming at specialization and those able to devote only a more limited amount of time to the subject. Fees range from two guineas for the introductory course to £60 for the "specialist" course. Full particulars can be obtained from the honorary lecture secretary, Institute of Medical Psychology, Malet Place, W.C.1.

Lectures on sectional or more popular lines have also been arranged for doctors, nurses, educational and social workers, the clergy, and the general public. One series will deal with "Psychology and Modern Problems," the lecturers including the new Dean of St. Paul's (Dr. W. R. Matthews), Professor C. G. Seligman, Professor Morris Ginsberg, Professor J. C. Flugel, and Dr. H. Crichton-Miller.

Scotland

Health and Housing

The sixtieth annual Congress of the Royal Sanitary Association of Scotland was held last week in the Albert Halls, Stirling. Mr. A. W. Ritchie, chief sanitary inspector, Edinburgh, in his presidential address, said that the housing conditions existing at the middle of last century were part of the unhappy consequences of the industrial revolution, which caused great numbers of people to flock into larger centres to find employment in the mills. These old buildings were erected with no regard for arrangement or for the most elementary sanitary requirements. As a consequence the death rate in 1876 was 20.9 per 1,000 of the population, as contrasted with 13.2 in 1933. The modern tendency in housing was towards simplification and economy without loss of security. Concerning sewage disposal, he said that remarkable developments had taken place in purification works, but it was regrettable that so many rivers still remained grossly polluted. Inquiries in this connexion, however, were being conducted by the Department of Health. The results following the transfer of slum dwellers to clearance areas had demonstrated beyond a doubt that improved environment was a very important factor in the furtherance of health and happiness. It was a mistake to suppose that these persons reduced their new dwellings to a level with the old; the proportion who failed to respond to the new surroundings was not more than 4 or 5 per cent.

Campaign against Tuberculosis

At the meeting on September 13th a resolution was unanimously adopted calling upon the Government to introduce legislation in the forthcoming Housing Bill for the rehousing of families in which tuberculosis was present. In the long discussion which followed on the campaign against tuberculosis, Councillor Mrs. Mann said medical opinion agreed that too much money was being spent on the treatment of tuberculosis and the development of sanatoria, and too little on housing with the same objective. In Glasgow, where £500,000 had been spent on the prevention and cure of tuberculosis, patients were brought back from sanatoria to sleep in one-apartment houses with six, seven, or eight other persons. It was an anomaly that thousands of slum dwellers might be removed and qualify for the grant of £2 10s. per head, but not even two tuberculous patients from an overcrowded area could be removed to obtain this grant, because there was no Act under which this could be effected. Dr. R. J. Peters, senior assistant medical officer of health in Glasgow, said that tuberculosis of bovine origin was a serious matter, but the type of infection which took origin in the human subject was more serious still. Science had put into their hands knowledge of the means of prevention of bovine tuberculosis, and it seemed strange that the lives of children were still being menaced by this disease. During the past twenty years much had been expended upon the control of tuberculosis. In England over £3,000,000 of public money was spent annually in this cause. In

Glasgow the amount spent was relatively higher; on an average each case of tuberculosis cost the ratepayers of that city about £100 for treatment and supervision. Newer methods of treatment of pulmonary tuberculosis had altered the views of clinical officers on the question of admission to hospital, and the improvement in social conditions had rendered the need for extensive isolation less urgent than before. The sanatorium and the local authority hospital had had one drawback in an unfortunate measure of divorcement between tuberculosis and general medicine. Those who were occupied with tuberculosis work did not come into contact with workers in other fields of medicine as freely as they should, but this could to some extent be remedied by allowing a few cases to pass through the voluntary general hospitals. Dr. J. P. Dunn, medical officer of health for Dumfries, pointed out that although the incidence of tuberculosis was declining, it was still killing 30,000 people every year, and costing the nation over £2,000,000 in residential treatment alone. In Britain every year 2,000 children died from infection with bovine tuberculosis, and some 4,000 suffered permanent crippling. Major J. G. McGregor, county veterinary officer, Stirlingshire, said that the incidence of bovine tuberculosis among milk cows was very high, for at least 40 per cent. of all the dairy cows in the area of the Scottish Milk Marketing Board would react to the tuberculin test. The number, however, that excreted tubercle bacilli in their milk was small; it was estimated that only about 0.5 per cent. of cows yielded tuberculous milk. The incidence of tuberculous infection in raw milk had been found to be in the neighbourhood of 10 per cent. of samples, but Certified and Grade A (T.T.) milk had been shown, in an investigation by the Department of Health, to be practically safe. Pasteurization of all other milk had been suggested as a solution of the problem, and the Medical Research Council had come to the conclusion that if this was properly carried out it had no seriously damaging effect upon the nutritive qualities of the milk. Mr. W. Y. Park, sanitary inspector, Rutherglen, speaking of the conditions which favoured the onset of tuberculosis, mentioned, in addition to poor housing conditions and infected milk supply, the atmospheric pollution of towns. There was no law against domestic smoke, and yet three-fourths of the total atmospheric pollution was due to the house chimney. In the opinion of Dr. McMichael, Paisley, there was a clear necessity for a definite policy on the question of housing tuberculous families in industrial areas. Investigation during the last five years into the sleeping accommodation of 754 tuberculous persons showed that 63 per cent. shared a bed, 21 per cent. occupied a bed alone but shared a room, and only 15 per cent. were the sole occupants of a room. In the light of such conditions the local authority of Paisley had some years ago decided to make a special effort, and had rehoused 182 tuberculous families, or 20.9 per cent. of all the cases on its register.

Mental Health Services

On September 14th a discussion was introduced by Professor D. K. Henderson, physician-superintendent of the Royal Edinburgh Mental Hospital, upon a modern mental health service. He said that the maintenance of mental health in the community was one of the greatest outstanding problems. This problem was concerned with several well-defined groups, including: (1) the mentally disordered, who spent part of their lives in mental hospitals; (2) the mentally defective, of whom many remained in institutions throughout life; (3) the delinquent and criminal, of whom a number suffered from mental disorder, while others required investigation to fit them for social life; (4) the border-line psychoneurotics who might be

dissatisfied, hysterical, neurotic, or anxious, and were in need of help and treatment; (5) unsatisfactory individuals who were social misfits, including drug addicts, alcoholics, prostitutes, and many of the unemployable. In England and Wales there were about 150,000 mentally disordered persons, with 20,000 more in Scotland, while mental defectives approximated to 8.56 per 1,000 of the population. In London about one person out of 200 was mentally deranged, and one person out of 274 was a mental defective. In Scotland, according to the General Board of Control, since 1858 the number of insane persons had increased by 235 per cent., while the population had increased by only 62 per cent. These figures were bad enough, but they would be still more appalling if they included all those seriously disordered persons who were maintained outside institutions, but who would benefit by greater supervision. Yet great advances in control had been made, and in Great Britain the mental hospitals caring for both rate-aided and private patients were second to none. Alarmists raised a cry for some all-embracing destructive policy which would solve the problem at one swoop. Such a policy was unthinkable and contrary to humanitarian instincts, and was dominated by fear. The continued policy of building more and larger institutions was also something which should be obviated. There must be a limit to segregation combined with training and employment, and the matter must be met on a wider and more constructive basis. While sterilization might be adopted in individual cases, its usefulness was more individual than racial, and there were so many pitfalls and complexities associated with it and so many cogent arguments against it that its use would be extremely limited. A positive eugenic policy, on the other hand, was an attempt to increase the number of children above medium intelligence by encouraging the growth and development of healthy families. To obviate the economic aspects of this, a scheme of family allowances had been suggested whereby parents should receive financial support for healthy children. To-day provision was made for the unemployed and unemployable, while little or nothing was done for the people on whom the welfare of the nation depended. In the meantime they must apply themselves to the study and treatment of those who were unable to adjust themselves to the artificial standards of society. Most of the trouble started in the cradle and the nursery long before school age. If the difficulties of nervous, highly strung, sensitive, and wayward children, who were socially unable to form satisfactory adaptations, were not corrected in childhood, they would never be corrected at all. Efforts should be made at this formative period to pluck out the roots of budding trouble by the co-operation of parents, teachers, ministers, social workers, school medical officers, and specialists. Many clinics for this purpose were in existence, and the speaker would like to see these co-ordinated and extended; at present there were too many working independently and covering much the same ground. The clinics dealing with the nervous and mental health of the child might well be grouped at the children's hospitals. Every mental hospital in the country ought to organize in its county town or other centre an out-patient clinic to which patients could have easy access. Further, a psychiatrist should be attached to juvenile courts; he might be helpful to many early offenders. Psychiatric clinics should be established, which would provide indoor and outdoor treatment for patients who needed careful observation and treatment, but who were not yet so seriously involved as to require the aid of a mental hospital. Dr. W. McAlister, medical superintendent of Bangour Village Asylum, referred to the fact that this was the first occasion on which the Sanitary Congress had had a discussion on mental health. He congratulated the association on lifting its eyes from the dismal subject of drains to the more salubrious subject

of brains, for in doing so it was coming into line with the great mass of the public whose conscience had been roused in this matter. In the last twenty-five years there had been a partial revolution against the ravages of mental disease. Local authorities, however, had not sufficiently taken advantage of existing legislation, for the Mental Deficiency Act of 1913 called upon them to ascertain the mental defectives within their own area, to arrange for special schooling for those who could profit by it, to provide institutional care for those who required it, and to assume control over defectives who were at large in the community. In Scotland in some counties the number of mental defectives had not yet been ascertained, and therefore the other three demands could not be fulfilled. He believed also that the medical profession was to blame, for they had allowed themselves to continue working under old traditions instead of stepping in at the early nervous stage and dealing with matters during formative years. Much research was required in mental disease which ought to be organized on a national scale. The key to the whole situation lay in the child, and all schools of psychology were now agreed on the supreme importance of early years. Dr. William Boyd, medical superintendent of Fife District Asylum, stated that the present fast pace of life was leading to a greater development of mental troubles. The Lunacy Act required to be altered in the direction of making asylums more of the nature of hospitals, and of removing the difference between pauper patients and others. Dr. Macgregor, medical officer of health for Glasgow, said that in regard to eugenics they must have more facts and more information. In Glasgow special wards were being created in the general hospitals which really amounted to psychiatric units, where, in addition to a study of early cases of mental disorder, all the medical and surgical skill in the institution was available. He believed this was the proper line on which such psychiatric units should develop.

Reports of Societies

ACUTE STREPTOCOCCAL THROAT INFECTIONS

On September 15th, in connexion with the two-day jubilee celebration of the Medical Officers of Schools Association held at Eastbourne, by invitation of the Mayor and Corporation and the Local Head Masters' Association, and under the presidency of Dr. J. A. H. BRINCKER, a paper (contributed conjointly by himself and Dr. FRED GRIFFITH) was read at the Town Hall by Dr. J. ALISON GLOVER, Senior Medical Officer, Board of Education, on "Acute Streptococcal Throat Infections."

Dr. Glover said that this subject was of perennial importance to both head master and school medical officer, as these infections of the throat constituted a continual source of anxiety. The most prevalent streptococcal disorder met with in schools was acute tonsillitis: it was both endemic and epidemic, and had an incubation period of two to four days. Its main incidence occurred at puberty, and while it was sometimes conveyed either by drinking milk or by the common use of tableware, handkerchiefs, or pencils, droplet infection was the usual method of transmission in schools. With the exception of the Klebs-Loeffler bacillus, the almost invariable causal organism in sore throat was the haemolytic streptococcus (*S. pyogenes*). The attack rate varied. It was 2.7 per cent. annually (1932) in the Royal Navy; at Guy's Hospital, taken over a series of years, 6.7 per cent. of those attending the casualty department for the first time came on account of it; while Captain Dudley found an attack rate of 4.8 per cent. per term at the Royal Hospital School, Greenwich. Its seriousness was largely derived from the various complications which might ensue, such as otitis media, mastoiditis, meningitis, septicaemia, and pneumonia, and, more rarely, acute rheumatism and

nephritis. It was also liable to be coincident with measles outbreaks. It had long been recognized that cases of tonsillitis without rash occurred during epidemics of scarlatina side by side with cases which exhibited the rash fully developed. Mantle, in 1887, pointed out the close alliance of the conditions found in sore throat epidemics and those present in cases of scarlatina, and this was confirmed by the serological work of Dr. F. Griffith, the collaborator in this paper.

Haemolytic streptococci in the throat produced varying clinical pictures in different persons, and these differences might be seen in boys in the same dormitory. In one boy there might be a feverish pharyngitis, in another tonsillitis, in a third scarlet fever, while another would be a healthy carrier. *S. pyogenes* had been found in varying proportions in all communities examined, the percentage varying with season and hygienic surroundings. During school epidemics the "healthy" carrier rate might be very high. Certain serological types of this *pyogenes* group seemed specially equipped to produce the complete scarlatinal syndrome. Dr. Glover said that members of the profession as well as the laity were still inclined to view an epidemic of scarlet fever as no more than a number of cases of a well-defined clinical type, devoting their energies to tracing the spread from case to case, in the belief that the isolation of all suspected cases would stay the progress of the epidemic. Sometimes results seemed to justify this attitude, but often the matter proved to be much more complex, particularly in cases in which the toxigenicity of the infecting strain was low and when part of the school population was Dick-immune. In such outbreaks as these the epidemic could be called a carrier epidemic. By diagrams Dr. Glover explained the epidemiology of streptococcal epidemics in nine schools, correlating the clinical and epidemiological features with Dr. Griffith's serological findings of the infecting types of streptococcus.

Otitis media caused school doctors much anxiety; mostly it was a sequel following tonsillitis, influenza, scarlet fever, or measles. It was probable that at least three-fifths of the cases of otitis media occurring in schools were due to haemolytic streptococci.

Dr. Glover proceeded to consider the importance of the dormitory as a factor in the spread of these epidemics. While the incidence of tonsillitis, measles, and influenza during the four years 1930-33 inclusive was substantially the same for boys and for girls in well-to-do public boarding schools—that is, in the cases investigated during the inquiry by the Medical Research Council into epidemics in schools—the incidence of serious complications due to streptococci and pneumococci was found to be significantly lower in the case of girls. Among the causes suggested to account for this difference were: the greater care given to girls, their superior discretion when ill and greater watchfulness over their health, and their better nutrition. Dr. Glover considered, however, that the main cause for the better figures in regard to girls was that the latter slept in large and well-ventilated cubicles, whilst most boys, on the other hand, slept in dormitories, many of them of somewhat antique design. The speaker, though a strong advocate of pure water for baths, did not attribute great importance to swimming as a factor in the production of otitis media in schools, as by far the highest incidence of ear trouble occurred in the Lent term, when there was but little swimming. In the well-nurtured children in public schools acute rheumatism was a less common complication of tonsillitis than was otitis media. For the production of acute rheumatism some further, at present unknown, factor seemed to be needed in addition to infection by haemolytic streptococci; it was possible that this factor was some kind of vitamin deficiency.

Dealing finally with the question of prevention, Dr. Glover said that the occurrence of epidemics of tonsillitis in schools generally indicated the existence of unsatisfactory conditions in regard to hygiene, either in the school itself or in the sick-room or sanatorium. When these epidemics occurred there was usually a high carrier rate of haemolytic streptococci, and there was usually also some reason to suspect that the environmental con-

ditions were such as to facilitate the transmission of the infection. In most of these epidemics the infection was wafted in droplet form from one nasopharynx to another, in either dormitory, classroom, common room, changing-room, dining-room, tuck-shop, or chapel. Of these, the dormitory seemed to be the most important, for here the proximity of boy to boy was uninterrupted for several hours continuously, aided by closed doors and, in bad weather, many closed windows. During the last twenty years the Board of Education had laid down for observance in schools certain excellent minima. It required that for dormitories there should be a space of at least three feet between beds, a floor area per bed of not less than 65 square feet, and a cubic space of not less than 700 cubic feet per bed. Ventilation must be adequate and "through," by arranging windows on the opposite sides of a room. In the case of cubicles, if partitions were not carried to the ceiling there should be an allowance of 65 square feet and 700 cubic feet. When partitions were carried to the ceiling the figure should be 100 square feet and 1,000 cubic feet respectively. He said it was especially important to avoid overcrowding the sanatorium when an epidemic occurred; patients in such an event should have their beds separated by certainly not less than six feet.

Dr. Glover's reference to prophylactic immunization was omitted owing to pressure of time.

DISCUSSION

The PRESIDENT said there were a number of aspects of this question apart from the bacteriological. The school medical officer had to deal with these cases from the beginning; his was the anxiety, and he had to satisfy parents that everything possible was being done for their boys. The point of view of the general practitioner also had to be considered.

Dr. L. R. LEMPRIERE (Haileybury) emphasized the point that at the time of epidemic outbreaks it became for the school medical officer a matter of personal activity on the right lines. These septic sore throats had always been a cause of anxiety, and his observation gave him the view that these school visitations were recently on the increase. How to prevent these cases did not yet seem clear, especially as there appeared to be different types of causal organism. There had been a great improvement in the general hygiene of school premises; especially was that so in county council schools in the last forty years. He regretted there did not seem to be much improvement in the personal hygiene of the average public school boy; what had happened in regard to the school girl he was not in a position to say. The nose of the usual boy was a "cesspool." In comparison with tonsillitis there had been a small development of scarlet fever. He had long thought that the worst throat epidemics were in schools which were built on a clay soil.

Mr. THORNTON (Mayor of Eastbourne) said he was particularly interested in the question of possible harm from bathing, especially as a cause of ear disease. Dr. Willoughby had been instrumental in placing the Eastbourne bathing establishments on a satisfactory basis. His own view, as a schoolmaster, was that bathing had something to do with the causation of otitis media, especially sea bathing. It was probably largely due to boys jumping into the water feet foremost; accordingly he always urged boys to pinch their nose to keep out the water, and this was found to be a valuable deterrent. Gargling every morning was also a great advantage. Dr. LILIAS JEFFRIES was of opinion that bathing was responsible for some cases of otitis media. She was an advocate of the cubicle system for sleeping, though she had no figures to show a greater freedom from nasopharyngeal disease under that system as compared with dormitories. She was sure many school dormitories were imperfectly ventilated. She also strongly felt that sufficient stress was not always laid on having all milk consumed in schools pasteurized.

Dr. W. G. WILLOUGHBY (Eastbourne) said his view agreed with that of Dr. Lempriere that these streptococcal throat epidemics were on the increase in schools, especially since the war. On the other hand, the scarlet

fever now seen was certainly less severe than formerly. He stressed the need in dormitories and classrooms of having the air frequently renewed; the window space should be, in his view, one-tenth of the total floor space, and it should be possible to open half of every window. While agreeing with a daily throat gargle, he did not favour nasal syringing as a routine, owing to the delicacy of the nasal mucous membranes. In Eastbourne the policy of isolation of every suspected case of scarlet fever had been most successful. It would be a great boon to have for use a preventive serum for inoculation against the haemolytic streptococcus.

Dr. W. H. BRADLEY (Downshire School) said his experience had convinced him that overcrowding was the most important factor in the spread of streptococcal diseases. In one school of which he had knowledge its population was reduced from 340 to 220, and the result of the generous spacing this gave to each boy was that the medical officer had little to do. Owing to the variety of the clinical pictures produced in these epidemics he urged continual watchfulness and study on the part of the school medical officer. Dr. E. H. R. HARRIES (N.E. Fever Hospital) said that the throats of a large number of admissions to his hospital yielded a pure culture of haemolytic streptococcus, and he advocated early testing for this as a quick diagnostic measure, as the haemolysis was soon evident to the naked eye. The use of scarlet fever antitoxin should be general, even in mild cases; it certainly reduced the complication rate.

Dr. E. K. LE FLEMING said the great problem awaiting solution was as to how resistance to the streptococcus was lost, and how it could best be regained. Overcrowding he placed first among the causes favouring the spread of these epidemics in schools, and he thought that if open-air dormitories were universal quite 90 per cent. of these troubles would be solved, though admittedly both parents and head masters would first need to be educated as to the benefit of the measure. He asked that a disease chart might be drawn up for use in schools; perhaps the Association would collaborate with the Ministry of Health to this end. Dr. R. E. SMITH (Rugby School) thought parents should be told that much could be done to prevent scarlet fever epidemics; many young boys had not become immunized to the disease before being sent to the public school, and the speaker thought parents should have this done before sending their sons to school. Dr. W. ATTLEE (Eton) pointed out that separate sleeping rooms was the rule at Eton, and there not more than two or three cases of haemolytic streptococcus throat trouble were seen at a time; there was no spread in epidemic form. If more thorough ventilation of schools were carried out improved heating should be an accompaniment.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION

The third quinquennial congress of the Medical Women's International Association was held this year in Stockholm from August 7th to 12th, by invitation of the Swedish Medical Women's Association. The meeting was preceded by a three-day visit to Copenhagen, where members of the congress were entertained by the Danish Association, and was followed by a visit to Helsingfors, by invitation of the medical women of Finland. Official delegates were present representing seventeen different countries, including fifty-three members from Great Britain and thirty-three from the United States. There were also representatives from Japan and India, as well as from the principal European countries. The total attendance exceeded two hundred. At the scientific sessions the subjects for discussion were: (1) The effects of physical education on the development, structure, and functions of the female body; (2) birth control.

The *rapporteurs généraux* for the first question were Dr. Bertha van Hoosen (U.S.A.), Dr. Lolhoffel-Lowensprung (Germany), and Dr. Lofja Zabawska (Poland). For the second question they were Dr. Alma Sundquist (Sweden), Professor Dame Louise McIlroy (Great Britain), and Dr. Dewetterova (Czechoslovakia). Their reports

were based on replies to questionnaires sent out to medical women with special experience in the subjects involved, each *rapporteur* dealing with those from a group of countries. The *rapporteurs* summarized the findings contained in their reports, which had previously been circulated. Writers of papers were asked to speak briefly, and the questions were then opened for public discussion. Both subjects aroused a great deal of interest.

In regard to the question of physical education for women there was remarkable unanimity of opinion as to its value. The alleged risks and dangers were shown to have little or no foundation in fact, and the favourable influence of exercise on menstruation was generally accepted. A resolution was passed by the whole association to the effect that the International Medical Women's Association regarded the scientific research and control of physical education for women, carried out in collaboration with teachers of physical education and the various organizations for sport and physical education, as one of its most important duties.

As to birth control there was of necessity considerable difference of opinion. In the Roman Catholic countries of Europe birth control, except for strictly medical reasons, is not permitted, whereas in certain other countries it is recognized and even encouraged by the State for eugenic and even economic and social reasons. Other countries, again, stand in an intermediate position. The discussion ranged from questions of principle to the details of contraceptive measures, and in spite of the inevitable differences in point of view it was extremely friendly, and pursued in the true spirit of scientific inquiry. It was decided that at this juncture it would be inadvisable to formulate any general resolution, but the council wished it to be put on record that it was satisfied that the discussion had been of international value from a scientific point of view.

It was resolved that the next congress should be held in July, 1937. The subjects chosen for discussion on that occasion were: (1) cancer in women, and (2) maternal mortality. It was decided that the international secretariat should remain in Paris for the next three-year period. Dr. Alma Sundquist was elected president, Mme. Montreuil-Straus (France) was re-elected honorary secretary, and Miss Louisa Martindale, formerly president of the British Medical Women's Federation and vice-president of the International Medical Women's Association (Great Britain), was elected honorary treasurer. The six international vice-presidents were Mme. Dr. Thuillier-Landry, ex-president (France), Mme. Dr. Bauer (Austria), Dr. Dagny Bagne (Norway), Dr. Doris Odum (Great Britain), Dr. Taylor Jones (U.S.A.), and Dr. Margaret Balfour (India).

The inaugural meeting of the congress was addressed by Herr Gustav Moller (Minister of Social Affairs), Herr Torsten Nothin (Governor-General of the City of Stockholm), and Herr Dr. Nils Hellstrom (Chief of the Royal Medical Board). The members of the congress were most hospitably entertained at Stockholm, Copenhagen, and Helsingfors. In all the three countries the fullest opportunities were afforded for visiting the principal hospitals and institutions, and the extremely modern and well-equipped hospitals and social organizations afforded great interest and instruction. Since Finland has become an independent country she has made enormous strides in her medical and social services, and her modern hospitals are among the best in Europe. The beautiful cities, with their fine public buildings, extremely modern in type, and the warm hospitality which they received will make the congress a memorable one for all those who were fortunate enough to take part in it.

The report dealing with the last Remembrance Day appeal for Earl Haig's Fund shows that £511,853 was contributed on Poppy Day, 1933—an increase of nearly £30,000 over the figure for the previous year. Many committees throughout the country have already started their work of local organization for the 1934 Remembrance Day appeal, which this year will be made on Saturday, November 10th.

CORRESPONDENCE

Stanley Melville Memorial

SIR.—The dangers of x-ray work were brought home vividly to the medical world by the death of several of our pioneer radiologists. In 1921 a letter to the *Times* announced the formation of a special committee to advise on these dangers. In this action the late Dr. Stanley Melville played a very prominent part. This X-Ray and Radium Protection Committee was the first in the world to draw up recommendations for safeguarding those who work with these agents. Their value may be gauged by the fact that they formed the basis of the recommendations adopted at the Stockholm International Radiological Congress in 1928.

Dr. Stanley Melville took a most important but unobtrusive part in all that concerned medical radiology. He was one of those who worked for the establishment of the Diploma in Medical Radiology and Electrology (D.M.R.E.) at Cambridge in 1919, and subsequently the teaching and examinations connected with it were his constant care. The bilingual congress of 1922 and the First International Congress of Radiology in London in 1925 were largely due to his initiative, as was also the formation of the British Institute of Radiology, with which the Röntgen Society was eventually incorporated. He did much for the welfare of the lay worker, and took a prominent part in founding the Society of Radiographers. Sadly handicapped physically, and often suffering as the result of dermatitis incurred in the early days, Melville never spared himself when any work for medical radiology had to be done; that he should be ever ready to step into the breach seemed to be the natural course of events.

Some of your readers may feel that his services should be recognized and perpetuated by a suitable memorial, such as a travelling fellowship in radiology. Donations, however small, for the purpose will be gratefully acknowledged. At a later date a meeting of those subscribing to the fund will be called in order to decide what form the memorial shall take and how the funds subscribed shall be administered.—We are, etc.,

HUMPHRY ROLLESTON (*Chairman*).

RUTHERFORD (Cambridge).

L. S. T. BURRELL (Brompton Hospital).

G. W. C. KAYE (National Physical Laboratory).

G. W. MITCHELL (St. George's Hospital).

R. S. PATERSON (Radiology Section, Royal Society of Medicine).

LEO. A. ROWDEN (Society of Radiographers).

SIDNEY RUSS (British X-Ray and Radium Protection Committee).

J. DUNCAN WHITE } (British Institute of Radiology)
A. E. BARCLAY } (Honorary Secretaries).

32, Welbeck Street, W.1, Sept. 14th.

Preliminary Ligation in Toxic Goitre

SIR.—It is clear from the correspondence in the *Journal* of June 30th, July 14th, 21st, and 28th, that there is a considerable divergence of opinion on the advisability of preliminary ligation in cases of toxic goitre. While Sir Thomas Dunhill, Professor Wilkie, and Mr. Geoffrey Keynes favour the ligation procedure, Mr. Cecil A. Joll takes a much more guarded view.

It will be agreed that the best means to ensure a low mortality is to leave so little thyroid tissue that severe post-operative reactions cannot occur, and this involves removal of about seven-eighths of the gland in the majority of cases. In the very toxic patients, although it may be unwise to carry out this operation in the one

stage, I think, nevertheless, that at least a large portion of one lobe should be removed under these circumstances, and the post-operative reaction will depend, to a great extent, on how much thyroid is left behind. I believe that the ligation operation cannot be relied upon to reduce to any great extent the amount of active gland, and for this reason the first stage of the operation in a very toxic case should include more than simple ligation of the vessels.

That these views are not without support is evident from a study of the literature on the subject. H. M. Richter, in *Surgery, Gynecology and Obstetrics* (vol. xlix, p. 67), reports a series of 500 consecutive cases of toxic goitre subjected to operation with one death only. He is of the opinion that preliminary ligation should not be done, and aims at carrying out the operation in one stage only. A series of cases so successfully dealt with cannot be ignored. Again, Greene and Mora (*ibid.*, 1931, vol. liii) report 1,025 consecutive thyroidectomies for toxic goitre in one-stage operations with a mortality of 0.29 per cent., and also a series of twenty-six cases in children in which a one-stage operation was performed with no deaths. The preliminary ligation method is not practised by them. F. H. Lahey, in the *New England Journal of Medicine* (1929, p. 909), basing his views on over 4,000 cases of toxic goitre, makes the following statement:

"Due to the preliminary use of iodine, multiple stage operations which we have previously advocated have markedly diminished in number, and when done are now limited at the most to a two-stage procedure, the partial removal of one lobe, the patient returning to hospital at the end of six weeks for the partial removal of the remaining lobe."

In 1924 fifty-seven operations for preliminary ligation were carried out in the Lahey clinic, but since then the operation is no longer regarded with favour, and in 1928, although there were 618 operations for toxic goitre, in no case was preliminary ligation considered advisable, and yet there was only one death in this group. In this country W. H. C. Romanis (*British Medical Journal*, January 21st, 1933, p. 87), reporting on 900 cases with a mortality of 2.5 per cent., recommends a two-stage operation, if the patient is exceedingly ill, in which one lobe is removed on the first occasion and part of the remaining lobe later. He does not support the operation of preliminary ligation.

Mr. Cecil A. Joll very rightly points out that:

"It must not be forgotten that, minor operation as it is, preliminary ligation has an appreciable mortality, and there is by no means a negligible minority in which the operation either aggravates the progress of the disease, or at any rate entirely fails to check it."

The risks are illustrated in an article by H. L. Wallace and L. B. Wevill in the *Edinburgh Medical Journal* (December, 1933), who report fourteen cases of preliminary ligation with three deaths, two of which occurred in severe cases and one in a mild case, death being due in this case to haemolytic jaundice. Mr. Geoffrey Keynes, although an exponent of the operation, used preliminary ligation in only eight of his series of 220 cases of toxic goitre. One of this group of eight died; he gives details of four of the remaining seven cases in his article of May 12th on "Avertin Narcosis," and certainly in two considerable improvement took place within a few days of the operation. This happy result was not experienced with the other two, one of whom barely survived the reaction following the operation, and the other, in spite of ligation of all four thyroid arteries, remained in a very serious condition with no improvement. In both of these cases it is interesting to note that, although the patients had in no way benefited by ligation and were very gravely ill, yet both these cases responded very satisfactorily to a two-stage operation consisting of removal of one lobe

fever now seen was certainly less severe than formerly. He stressed the need in dormitories and classrooms of having the air frequently renewed; the window space should be, in his view, one-tenth of the total floor space, and it should be possible to open half of every window. While agreeing with a daily throat gargle, he did not favour nasal syringing as a routine, owing to the delicacy of the nasal mucous membranes. In Eastbourne the policy of isolation of every suspected case of scarlet fever had been most successful. It would be a great boon to have for use a preventive serum for inoculation against the haemolytic streptococcus.

Dr. W. H. BRADLEY (Downshire School) said his experience had convinced him that overcrowding was the most important factor in the spread of streptococcal diseases. In one school of which he had knowledge its population was reduced from 340 to 220, and the result of the generous spacing this gave to each boy was that the medical officer had little to do. Owing to the variety of the clinical pictures produced in these epidemics he urged continual watchfulness and study on the part of the school medical officer. Dr. E. H. R. HARRIES (N.E. Fever Hospital) said that the throats of a large number of admissions to his hospital yielded a pure culture of haemolytic streptococcus, and he advocated early testing for this as a quick diagnostic measure, as the haemolysis was soon evident to the naked eye. The use of scarlet fever antitoxin should be general, even in mild cases; it certainly reduced the complication rate.

Dr. E. K. LE FLEMING said the great problem awaiting solution was as to how resistance to the streptococcus was lost, and how it could best be regained. Overcrowding he placed first among the causes favouring the spread of these epidemics in schools, and he thought that if open-air dormitories were universal quite 90 per cent. of these troubles would be solved, though admittedly both parents and head masters would first need to be educated as to the benefit of the measure. He asked that a disease chart might be drawn up for use in schools; perhaps the Association would collaborate with the Ministry of Health to this end. Dr. R. E. SMITH (Rugby School) thought parents should be told that much could be done to prevent scarlet fever epidemics; many young boys had not become immunized to the disease before being sent to the public school, and the speaker thought parents should have this done before sending their sons to school. Dr. W. ATTLEE (Eton) pointed out that separate sleeping rooms was the rule at Eton, and there not more than two or three cases of haemolytic streptococcus throat trouble were seen at a time; there was no spread in epidemic form. If more thorough ventilation of schools were carried out improved heating should be an accompaniment.

MEDICAL WOMEN'S INTERNATIONAL ASSOCIATION

The third quinquennial congress of the Medical Women's International Association was held this year in Stockholm from August 7th to 12th, by invitation of the Swedish Medical Women's Association. The meeting was preceded by a three-day visit to Copenhagen, where members of the congress were entertained by the Danish Association, and was followed by a visit to Helsingfors, by invitation of the medical women of Finland. Official delegates were present representing seventeen different countries, including fifty-three members from Great Britain and thirty-three from the United States. There were also representatives from Japan and India, as well as from the principal European countries. The total attendance exceeded two hundred. At the scientific sessions the subjects for discussion were: (1) The effects of physical education on the development, structure, and functions of the female body; (2) birth control.

The *rapporteurs généraux* for the first question were Dr. Bertha van Hoosen (U.S.A.), Dr. Lohoffel-Lowensprung (Germany), and Dr. Lofja Zabawska (Poland). For the second question they were Dr. Alma Sundquist (Sweden), Professor Dame Louise McIlroy (Great Britain), and Dr. Dewetterova (Czechoslovakia). Their reports

were based on replies to questionnaires sent out to medical women with special experience in the subjects involved, each *rapporteur* dealing with those from a group of countries. The *rapporteurs* summarized the findings contained in their reports, which had previously been circulated. Writers of papers were asked to speak briefly, and the questions were then opened for public discussion. Both subjects aroused a great deal of interest.

In regard to the question of physical education for women there was remarkable unanimity of opinion as to its value. The alleged risks and dangers were shown to have little or no foundation in fact, and the favourable influence of exercise on menstruation was generally accepted. A resolution was passed by the whole association to the effect that the International Medical Women's Association regarded the scientific research and control of physical education for women, carried out in collaboration with teachers of physical education and the various organizations for sport and physical education, as one of its most important duties.

As to birth control there was of necessity considerable difference of opinion. In the Roman Catholic countries of Europe birth control, except for strictly medical reasons, is not permitted, whereas in certain other countries it is recognized and even encouraged by the State for eugenic and even economic and social reasons. Other countries, again, stand in an intermediate position. The discussion ranged from questions of principle to the details of contraceptive measures, and in spite of the inevitable differences in point of view it was extremely friendly, and pursued in the true spirit of scientific inquiry. It was decided that at this juncture it would be inadvisable to formulate any general resolution, but the council wished it to be put on record that it was satisfied that the discussion had been of international value from a scientific point of view.

It was resolved that the next congress should be held in July, 1937. The subjects chosen for discussion on that occasion were: (1) cancer in women, and (2) maternal mortality. It was decided that the international secretariat should remain in Paris for the next three-year period. Dr. Alma Sundquist was elected president, Mme. Montreuil-Straus (France) was re-elected honorary secretary, and Miss Louisa Martindale, formerly president of the British Medical Women's Federation and vice-president of the International Medical Women's Association (Great Britain), was elected honorary treasurer. The six international vice-presidents were Mme. Dr. Thuillier-Landry, ex-president (France), Mme. Dr. Bauer (Austria), Dr. Dagny Bagnø (Norway), Dr. Doris Odum (Great Britain), Dr. Taylor Jones (U.S.A.), and Dr. Margaret Balfour (India).

The inaugural meeting of the congress was addressed by Herr Gustav Møller (Minister of Social Affairs), Herr Torsten Nothin (Governor-General of the City of Stockholm), and Herr Dr. Nils Hellström (Chief of the Royal Medical Board). The members of the congress were most hospitably entertained at Stockholm, Copenhagen, and Helsingfors. In all the three countries the fullest opportunities were afforded for visiting the principal hospitals and institutions, and the extremely modern and well-equipped hospitals and social organizations afforded great interest and instruction. Since Finland has become an independent country she has made enormous strides in her medical and social services, and her modern hospitals are among the best in Europe. The beautiful cities, with their fine public buildings, extremely modern in type, and the warm hospitality which they received will make the congress a memorable one for all those who were fortunate enough to take part in it.

The report dealing with the last Remembrance Day appeal for Earl Haig's Fund shows that £511,853 was contributed on Poppy Day, 1933—an increase of nearly £30,000 over the figure for the previous year. Many committees throughout the country have already started their work of local organization for the 1934 Remembrance Day appeal, which this year will be made on Saturday, November 10th.

CORRESPONDENCE

Stanley Melville Memorial

SIR,—The dangers of x-ray work were brought home vividly to the medical world by the death of several of our pioneer radiologists. In 1921 a letter to the *Times* announced the formation of a special committee to advise on these dangers. In this action the late Dr. Stanley Melville played a very prominent part. This X-Ray and Radium Protection Committee was the first in the world to draw up recommendations for safeguarding those who work with these agents. Their value may be gauged by the fact that they formed the basis of the recommendations adopted at the Stockholm International Radiological Congress in 1928.

Dr. Stanley Melville took a most important but unobtrusive part in all that concerned medical radiology. He was one of those who worked for the establishment of the Diploma in Medical Radiology and Electrology (D.M.R.E.) at Cambridge in 1919, and subsequently the teaching and examinations connected with it were his constant care. The bilingual congress of 1922 and the First International Congress of Radiology in London in 1925 were largely due to his initiative, as was also the formation of the British Institute of Radiology, with which the Röntgen Society was eventually incorporated. He did much for the welfare of the lay worker, and took a prominent part in founding the Society of Radiographers. Sadly handicapped physically, and often suffering as the result of dermatitis incurred in the early days, Melville never spared himself when any work for medical radiology had to be done; that he should be ever ready to step into the breach seemed to be the natural course of events.

Some of your readers may feel that his services should be recognized and perpetuated by a suitable memorial, such as a travelling fellowship in radiology. Donations, however small, for the purpose will be gratefully acknowledged. At a later date a meeting of those subscribing to the fund will be called in order to decide what form the memorial shall take and how the funds subscribed shall be administered.—We are, etc.,

HUMPHRY ROLLESTON (*Chairman*).

RUTHERFORD (Cambridge).

Preliminary Ligation in Toxic Goitre

SIR,—It is clear from the correspondence in the *Journal* of June 30th, July 14th, 21st, and 28th, that there is a considerable divergence of opinion on the advisability of preliminary ligation in cases of toxic goitre. While Sir Thomas Dunhill, Professor Wilkie, and Mr. Geoffrey Keynes favour the ligation procedure, Mr. Cecil A. Joll takes a much more guarded view.

It will be agreed that the best means to ensure a low mortality is to leave so little thyroid tissue that severe post-operative reactions cannot occur, and this involves removal of about seven-eighths of the gland in the majority of cases. In the very toxic patients, although it may be unwise to carry out this operation in the one

stage, I think, nevertheless, that at least a large portion of one lobe should be removed under these circumstances, and the post-operative reaction will depend, to a great extent, on how much thyroid is left behind. I believe that the ligation operation cannot be relied upon to reduce to any great extent the amount of active gland, and for this reason the first stage of the operation in a very toxic case should include more than simple ligation of the vessels.

That these views are not without support is evident from a study of the literature on the subject. H. M. Richter, in *Surgery, Gynecology and Obstetrics* (vol. xlix, p. 67), reports a series of 500 consecutive cases of toxic goitre subjected to operation with one death only. He is of the opinion that preliminary ligation should not be done, and aims at carrying out the operation in one stage only. A series of cases so successfully dealt with cannot be ignored. Again, Greene and Mora (*ibid.*, 1931, vol. liii) report 1,025 consecutive thyroidectomies for toxic goitre in one-stage operations with a mortality of 0.29 per cent., and also a series of twenty-six cases in children in which a one-stage operation was performed with no deaths. The preliminary ligation method is not practised by them. F. H. Lahey, in the *New England Journal of Medicine* (1929, p. 909), basing his views on over 4,000 cases of toxic goitre, makes the following statement:

"Due to the preliminary use of iodine, multiple stage operations which we have previously advocated have markedly diminished in number, and when done are now limited at the most to a two-stage procedure, the partial removal of one lobe, the patient returning to hospital at the end of six weeks for the partial removal of the remaining lobe."

In 1924 fifty-seven operations for preliminary ligation were carried out in the Lahey clinic, but since then the operation is no longer regarded with favour, and in 1928, although there were 618 operations for toxic goitre, in no case was preliminary ligation considered advisable, and yet there was only one death in this group. In this country W. H. C. Romanis (*British Medical Journal*, January 21st, 1933, p. 87), reporting on 900 cases with a mortality of 2.5 per cent., recommends a two-stage operation, if the patient is exceedingly ill, in which one lobe is removed on the first occasion and part of the remaining lobe later. He does not support the operation of preliminary ligation.

Mr. Cecil A. Joll very rightly points out that:

"it must not be forgotten that, minor operation as it is, preliminary ligation has an appreciable mortality, and there is by no means a negligible minority in which the operation either aggravates the progress of the disease, or at any rate entirely fails to check it."

The risks are illustrated in an article by H. L. Wallace and L. B. Wevill in the *Edinburgh Medical Journal* (December, 1933), who report fourteen cases of preliminary ligation with three deaths, two of which occurred in severe cases and one in a mild case, death being due in this case to haemolytic jaundice. Mr. Geoffrey Keynes, although an exponent of the operation, used preliminary ligation in only eight of his series of 220 cases of toxic goitre. One of this group of eight died; he gives details of four of the remaining seven cases in his article of May 12th on "Avertin Narcosis," and certainly in two considerable improvement took place within a few days of the operation. This happy result was not experienced with the other two, one of whom barely survived the reaction following the operation, and the other, in spite of ligation of all four thyroid arteries, remained in a very serious condition with no improvement. In both of these cases it is interesting to note that, although the patients had in no way benefited by ligation and were very gravely ill, yet both these cases responded very satisfactorily to a two-stage operation consisting of removal of one lobe

of the thyroid, followed later by removal of part of the remaining lobe. Thus of Mr. Keynes's eight cases, five were benefited by the operation, one died, and two received no benefit whatever, but nevertheless were later very successfully dealt with by excision of part of the gland.

In conclusion, I think there is good evidence to show that the more direct method of dealing with these cases by removal of at least a portion of the thyroid gland, should a two-stage operation be necessary, can be carried out with an extremely low mortality, and that preliminary ligation is a procedure which is associated with a grave risk in return for an uncertain result. I regret that Dr. Cunningham and I did not make it clear in our letter in the *Journal* of June 30th that in adult patients permission for operation is obtained during the early stages of the preliminary medical treatment, but that, once obtained, the subject is not discussed with the patient again, so as to avoid, as far as possible, unnecessary worry on his part. We are, of course, in agreement with Dr. Harold Cookson when he points out that it is illegal to operate without permission on a patient under 21 years of age unless certified insane. In Taylor's *Principles of Medical Jurisprudence* (eighth edition, vol. i, p. 109) it is stated that "no surgeon has a right to perform any operation against the will of the patient as long as the patient preserves consciousness and will." Possibly in some cases of very toxic goitre the terms "consciousness and will" might reasonably be interpreted to allow of an operation being performed without the patient's consent if the relatives are willing, but so far we have always obtained the patient's consent.—I am, etc.,

Liverpool, Sept. 13th. PHILIP HAWES, Ch.M., F.R.C.S.

Medical Education

Training for the Specialties

SIR,—Many thinking practitioners will find themselves heartily in agreement with the views expressed by Mr. Keith Monsarrat in your issue of September 8th (p. 488) and hope that further consideration may induce the powers that be to adopt his scheme rather than that which found favour with the majority of the Committee on Medical Education.

But if it is desirable that the medical graduate should have the benefit of a period of responsible clinical experience before taking up the duties of public practice I submit that it is almost equally important that no graduate should be permitted to embark on specialist and consultant practice without previous experience in general practice. My own observation and experience lead me to think that there are far too many so-called specialists for the health of the specialties and, it may be, also for the health of the public generally. Most men of experience will agree that it is impossible to deal adequately with any pathological condition of specific organs without consideration of the general health of the patient, and that the object of treatment should be directed to the patient suffering from the disease and not the morbid condition of one organ as though it were the only or even the chief consideration. The necessary experience can only be obtained in general practice, and it would, I believe, be greatly to the advantage of both our profession and our patients if some regulation could be devised to prevent anyone taking up a specialty until he had spent three years at least in an ordinary family practice. It might perhaps be made a condition for the M.R.C.P. or the F.R.C.S.

At present it seems as though any bright lad who has won a prize or two in his student career thinks himself too good for general practice either through his own

vanity or the flattery of foolish relatives or friends. One parent told me that he would not let his son become a doctor unless he could be a specialist. Such an outlook indicates that the object in view is to make money and secure a good social position, which is perhaps not infrequently the incentive rather than to "scorn delights, and live laborious days." Of course, I do not for a moment suggest that there are not examples of the latter outlook, and brilliant ones too, among the ranks of specialists, but the holders of the former point of view will never achieve the highest satisfaction that the practice of medicine can give.

It would be possible to adduce many more forcible arguments in support of my thesis, but they are more suitable for discussion *in camera* than in the Press. Many of the problems which faced the Central Ethical Committee in drawing up rules for consultation would not arise if some such regulation of specialism as I have indicated could be put into practice.—I am, etc.,

Derbyshire, Sept. 16th.

AN OLD GRADUATE.

B. coli Infections

SIR,—Professor Murray Lyon in his address (*British Medical Journal*, September 8th, p. 455) has dealt in a masterly way with this subject of everyday importance. His references to modern thought on this matter are very stimulating, but at the same time the views he has described would appear to be conflicting.

1. "The bile, though alkaline, is an excellent culture medium for the colon bacillus and similar organisms."

Why should the colon bacillus flourish in this alkaline medium when the best measures for eradicating it are massive doses of alkalis?

2. "Hurst has pointed out that where achlorhydria is present the contents of the duodenum are more alkaline—a condition favouring the growth of organisms."

And yet we give large doses of alkali to inhibit this growth! It would appear that the colon bacillus flourishes in an alkaline state of the bowel, but prefers a highly acid state of the urine.

3. "Excess fat in the diet favours penetration of the bowel wall by organisms; butter and eggs are therefore usually restricted."

Wherein, then, lies the value of a ketogenic diet, which contains large quantities of fat? That this diet has proved useful in clearing up many cases of chronic *B. coli* infection of the urinary tract (the primary focus being, as always, the bowel) there can be no doubt.

4. "Calomel in non-purgative doses is probably as useful a drug as any."

And yet its action is to increase the flow of bile, which, as has been said, is an excellent culture medium for the colon bacillus.—I am, etc.,

C. GORDON STRACHAN, M.B., F.R.C.P.Ed.

Cheam, Surrey, Sept. 12th

Increased Mortality from Diabetes

SIR,—With regard to the recent increased mortality from diabetes it has been suggested that it may not be a real increase, but may be due to the misleading character of the mortality statistics for this disease. It is well known that since the advent of insulin, owing to the greater activity in the routine examination for sugar in the urine and blood, many more diabetics have been discovered; but it does not necessarily follow that that means an increased mortality.

James Raglan Miller refutes this, as far as the U.S.A. statistics are concerned, in an article in the *New England Journal of Medicine* (ccviii, 490). He makes the statement that

"... the modern treatment of diabetes has reduced the number of deaths to such an extent that diabetes can now be considered as scarcely more than a serious handicap." And continues: "It is common knowledge that patients who have diabetes do not at present die because of their diabetes: diabetes, perhaps more than any other condition, seldom appears alone on the death certificate. Before the use of insulin it was in truth a frequent primary cause; in other words, it was diabetes which killed the patient. To-day it is frequently merely a condition which the patient is known to have had—a handicap, which even to the point of death is under perfect control."

Referring to death certification, Dr. Miller tells us that the "Manual of Joint Causes" is peculiar to the United States, being issued by the Central Bureau to regulate in a uniform manner the tabulation of deaths according to a definite scheme. He states:

"It will surprise most physicians to learn the extent to which diabetes takes precedence over other causes of death which appear on the death certificate. If diabetes is mentioned even as a secondary cause, together with any of the diagnoses in the following list, it will get the credit of causing the death."

He refers to a list of 113 diseases, including the following: erysipelas, encephalitis lethargica, acute rheumatic fever, epilepsy, lobar pneumonia, appendicitis, acute nephritis, pericarditis, and other diseases of the heart. He further claims that there is ever present in vital statistics, and from the beginning always has been, an attempt to make the incidence of mortality a measure or index of the incidence of morbidity.

Is it not possible that in recent years, in our own country, owing to the great attention that has been focused on diabetes and glycosuria, once the condition has been diagnosed in a patient, especially one of mature years, the fact is not forgotten: should the patient die from a condition wholly unrelated to diabetes, the glycosuric condition nevertheless finds mention on the death certificate, and thus a condition of morbidity becomes a cause of mortality?—I am, etc.,

Bramhall, Cheshire, Sept. 17th.

ALEX. FRASER.

Treatment of Fractures in the Newborn

SIR,—The annotation in your issue of August 25th (p. 363) discussing Drs. Eric Pritchard and Jean Smith's views on the treatment of fracture of the femur in the newly born, states that "the traditional method of dealing with neo-natal fracture of the femur is to bandage the thigh against the abdomen in the 'foetal' position. Nursing becomes very complicated in these circumstances." In July, 1908, after reading an account of twenty fractures of the thigh in the newly born, related by the late Sir Robert Jones, in all of which mal-union had taken place, I explained the treatment which Drs. Pritchard and Jean Smith describe as in the "foetal position." My article distinctly stated that the fractured leg comes to lie on the opposite side of the body; this is not in the foetal position. In my two cases related, the nursing, instead of being complicated, was so simple that one child, when the treatment had been applied, was placed on a pillow and two loose bandages applied round the pillow and child. The broken leg was out of the way, and the mother, raising the pillow on which the child lay, gave the child the breast. Another case subsequently was attended by a friend of mine in Belgium. He reported that the result was perfect and the

nursing easy. In all these cases the treatment was the essence of simplicity and the results all perfect.—I am, etc.,

Bolton-le-Sands, Sept. 12th.

JOHN EDMONDSON.

Peribronchial Tuberculosis

SIR,—In the *Journal* for September 8th (p. 461) Dr. Douglas Webster mentions—as an instance of diagnostic error—the fact that hundreds of recruits for the armies of Great Britain and America were wrongly rejected because of the confident radiological diagnosis of "peribronchial phthisis." This was twenty years ago: more recently (in May, 1927) a writer in the *American Journal of Roentgenology* was so incensed at the continuous stream of "well" patients sent into his sanatorium that he would hear of nothing less than the total abolition of the term "peribronchial tuberculosis."

Since I was the originator of this term (*Practitioner*, February, 1912, and *British Medical Journal*, August 31st, 1912), I hope you will be good enough to allow me a word of explanation. My thesis was a clear one, and, I think, expressed a rational and common-sense view. Finding (as I did) that pulmonary tuberculosis did not begin, as previously held, at the apices of the lungs but in the middle portions of the chest, opposite the roots—in a region where no physical signs could be made out in the early stages—I published my conclusions that pulmonary tuberculosis originated ordinarily as a catarrhal bronchitis and bronchiolitis. This earliest stage gives no x-ray signs, but it prepares the way for the all-important second stage. The walls of the small air tubes, having shed some of their lining epithelium, are no longer impervious to microbes, some of which (tubercle bacilli among them) pass through the weakened places into the peribronchial tissues, where leucocytes begin to assemble in groups for the purpose of dealing with them. These constitute the "fine mottling" which is the earliest x-ray sign of active disease. After this, one of three events may follow: (1) complete resolution and disappearance of the x-ray mottling; (2) healing by fibrous tissue formation, shown by widening and darkening of the linear shadows that radiate from the roots; (3) advancing disease—the "mottles" coalesce into blotches, then follow the advanced stages of caseation, ulceration, excavation, etc. While disease is advancing in the peribronchial tissues the glands at the root are gradually enlarging, as would be expected, seeing that the microbe-infected region is increasing in extent.

All this seems simple and rational and hardly open to controversy; but strangely enough the idea went abroad that pulmonary tuberculosis had been proved to start in the bronchial glands and spread from them along the air tubes—as soon would I have asserted that a "poisoned" finger started in the axillary glands and spread thence to the finger! Several writers invented theories to explain the remarkable phenomenon. The late Dr. R. Murray Leslie, for instance, invented the term "retropulsion of lymph" to explain it! Worse was to follow: for radiologists throughout the world began diagnosing peribronchial tuberculosis whenever they found dark blotches at the roots and "fibrous" bands radiating from the roots along the air tubes. I protest my innocence of blame for this. In my papers I drew special attention to these appearances in "healthy" chests, and explained them to be Nature's way of overcoming chronic microbic infection of the lungs. Further, I insisted that mottling was the only positive sign of active disease of the lungs.

Is mottling always tuberculous? Twenty years ago the answer was an unqualified "Yes"; to-day the reply is,

"Not always at first." The microbic invasion of the peribronchial tissues and the influx of leucocytes that follows (giving rise to mottling) is, I am convinced, nearly always micrococcal. Whether, and how soon, tubercle bacilli arrive there and begin to multiply depends on individual susceptibility to tuberculosis, and this may be inborn or acquired, or both—a fatal combination! Acquired susceptibility to tuberculosis, again, may be local or general. By "local" I mean that a chronic micrococcal infection of some portion of the lung impairs the resistance of that portion and renders it unnaturally susceptible to tuberculosis. By "general" I mean that a general toxæmia renders *all* tissues of the body prone to attack, since the toxæmia depreciates their natural resisting powers, and wherever tubercle bacilli lodge they are able to multiply and gain a firm foothold.—I am, etc.,

Pineapple Juice in Oedema

SIR,—I was much interested in the letter on the above subject in the *Journal* of September 8th (p. 492). During an outbreak of beri-beri in the gaol at Kuala Lumpur, Federated Malay States, in the years 1896 to 1898, the Chinese patients with dropsy invariably asked for pineapple. They said it was good for reducing the swelling. Their request was granted as a placebo, although I thought at the time it might act as a diuretic. The dropsy subsided, but, as they were given other diuretics, I could not attribute its disappearance entirely to the pineapple. I may state that Chinese patients suffering from dropsical beri-beri in other State hospitals also always asked for pineapple.—I am, etc.,

London, W.13, Sept. 17th.

A. J. McCLOSKEY, M.D.
Retired Senior Medical Officer, Selangor,
Federated Malay States.

"Port Sanitation and Common Sense"

SIR,—“Port Medical Officer” (September 8th, p. 491) has not perceived that my criticism of port authorities is almost entirely directed against *foreign* ones. He cannot have had much experience of these individuals, especially the Mediterranean and South American varieties, each of whom sees himself as a petty Cerberus in charge of the national safety, and to whom the mention of any kind of illness (even accidents!) arouses visions of dread epidemics, the ship being regarded as a sort of dung-heap which must forthwith be “disinfected” at a heavy charge to the owners.

In British ports a standard health questionnaire now at long last prevails in which the question, “Have you had any cases of illness on board whether of an infectious nature or not?” does not occur. “Port Medical Officer” does not see that I was referring here to cases which have occurred during the early part of a voyage and have since completely recovered. Why should the ship surgeon almost always be regarded as ignorant or inexperienced in regard to such cases of minor illness? Or, if he must be so regarded, why is no supervision exercised over the general practitioner ashore? Surely he is just as likely to miss ambulatory cases of small-pox, gonorrhoeal sequelae, and typhoid fever as the ship surgeon. What of the port medical officer himself? Is he entitled to claim medical omniscience?

Speaking from over ten years' sea-going experience in all parts of the world, I would say that the vast majority of these minor maladies are found to be mares' nests in regard to their danger to the community. In regard to the remainder, it is sad to relate that British law, being

the ass that it is, is sometimes woefully lacking. Witness the *Tuscania* affair. This ship landed a case of small-pox at Marseilles homewards. On arrival at Liverpool, though obviously contacts were on board, the ship could not be quarantined in the absence of actual cases. The result was a small epidemic ashore. Surely this requires amendment.

I trust that “Port Medical Officer” will not consider my remarks as directed against himself or other officers in British ports, whom I have almost invariably found sensible and friendly. It is the crass futilities and absurdities of foreign port sanitation procedures that I am up against. Surely the time has come when all such procedures should be made internationally uniform, and some system of checking a ship from point to point of its voyage be established in place of the present one of treating it as an “unknown quantity” at every port.—I am, etc.,

September 9th.

SHIP SURGEON.

Injuries of the Knee-Joint

SIR,—I have just read Dr. Stewart's letter (July 7th, (p. 40)). I am as unwilling as he is to perpetuate old heresies, but I am equally unwilling to subscribe to new ones. I hasten to assure him that I have never seen a joint “locked” in extension, but I read his letter to mean that he had. Absence of full extension presupposes some degree of flexion, and I suggest to him that in his cases the injury occurred during an attempt to re-extend the joint after a temporary flexion—that is, a rebracing under strain.

I welcome his suggestion of a slow-motion picture—if he is fortunate enough to obtain one I feel he will change his views. In the meantime perhaps he will describe the mechanism by which injury to a cartilage occurs in a fully extended knee-joint without severe damage to other joint structures.

I regret it was not clear that the last paragraph of my letter (June 23rd, p. 1142) referred to another part of Mr. McMurray's paper—that on crucial ligament injuries.—I am, etc.,

Newcastle-on-Tyne, Sept. 11th.

G. STEWART WOODMAN.

The Swab in Diphtheria Diagnosis

SIR,—I have read with considerable interest correspondence on this subject. As a medical officer of health and superintendent of a fever hospital I have seen a considerable number of cases of this disease during the past fifteen years, and I would like to make the following observations:

1. The diagnosis of diphtheria is by no means as simple as some of your correspondents would maintain; in the early stages of the disease I would defy any expert to diagnose many of the cases.

2. If a practitioner is in any doubt that a case is clinically diphtheria he should not only take a swab, planting the swab exactly upon the suspected area on the tonsil or elsewhere, but should also remember that in quite a number of cases a nasal swab will give a positive result where a throat swab will not. But if there is clinical evidence which renders the practitioner doubtful, as to the case being diphtheria it should at once be given at least 8,000 units of concentrated antitoxin, and if the history is longer than twenty-four hours such a dose should be doubled or trebled. Many a child's life would be saved if only this procedure were adopted.

3. It is my sad experience that in all cases of faucial diphtheria, if no antitoxin has been given prior to the fourth day of the disease, if they are true clinical

diphtheria, most will prove fatal: in fact, I always regard it in the nature of a miracle if such a case can be saved, no matter how much antitoxin is given or how it is given, whether intravenously or intramuscularly. The diphtheria toxin has got such an anchorage into the cardiac system that nothing will remove it; the throat may have cleared completely, but still the child will die.

4. There is no doubt whatever that certain cases of faucial diphtheria may give negative swabs—at any rate, throat swabs—although possibly the nasal swab, if taken, might have proved positive. Such patients, unless treated as diphtheria, will certainly die, and clinical evidence of the disease in these instances should certainly justify specific treatment. One such case I can recollect did not give a positive swab until the child had been ill for a fortnight and was on the point of death.—I am, etc.,

F. A. BELAM, M.D.,
Medical Officer of Health.

Guildford, Sept. 15th.

Obituary

THE LATE DR. C. W. HUTT

Dr. J. S. MANSON, Warrington, writes:

As an old personal friend of Hutt I would like to add a few words to the admirable obituary notice in your issue of September 8th (p. 493). Our friendship commenced during his stay in Warrington, and was maintained with the warmest affection for nearly twenty-five years. His Warrington friends rejoiced at the richly deserved success which he attained in the public health world, and it has been a great solace to me that we stayed together during the meeting of the Scientific Sections at Bournemouth in July. Although in poor health he came down from London to give his valuable contribution to the Public Health Section on immunization against diphtheria, and he was pleased that the Representative Body had authorized the setting up of a special committee on immunization.

He was secretary of the Public Health Section at the Edinburgh meeting in 1927, and although a loyal member of the Royal Institute of Public Health he had a great respect for the 'Public Health Section' of the British Medical Association, and thought that there might be closer co-operation between the two bodies. He often used to speak of his Continental visits, and his broadmindedness and facility of contact with foreigners made one regard him as a good European. He has been cut off when it seemed that further success and honour awaited him; and while all those who knew him deeply regret his loss, their sympathy goes out to his widow and family.

Dr. THACKER KING of Sandfield House, West Kirby, died on July 25th, aged 75. He studied medicine at Dublin, taking the L.R.C.P.I. and L.M. in 1883, and later the Durham M.D. Dr. King worked in West Kirby as a general practitioner for over forty-five years. He had three sons, two of whom he lost in the war, and one, Dr. George King, shortly after he had taken him as a partner. The loss of his sons was a great sorrow to him and Mrs. King, and one from which they never wholly recovered. Dr. Thacker King's success in practice was phenomenal, for he was endowed with the "physician's instinct," and this, coupled with a vast experience and knowledge derived from attending the sick and from extensive reading, rendered him invaluable to his numerous patients. He was a man of fine presence and strong personality, always ready and willing to visit and help anyone at any time, day or night. In addition, his courteous manners, sympathy, and honesty endeared him to friends and patients alike. His loss will be felt acutely by generations of people whom he treated and befriended, and the example he set of clean living, fairmindedness, and friendliness will live for many years. He had been a member of the Birkenhead Division of the British Medical Association for fifty years.

The Services

DEATHS IN THE SERVICES

Lieut.-Colonel Edward Pettingall Youngerman, Madras Medical Service (ret.), died on July 11th, aged 76. He was born on February 4th, 1858, and was educated at Edinburgh, where he graduated M.B., C.M. in 1879. Entering the I.M.S. as surgeon on October 1st, 1881, he became lieutenant-colonel after twenty years' service, and retired on March 2nd, 1907. He served in the Burma campaigns in 1885-6, receiving the frontier medal with a clasp. His whole service was passed in military employ in Madras regiments.

Colonel Claude Kyd Morgan, C.B., C.M.G., late R.A.M.C., died at London, Ontario, on August 10th, aged 62. He was the son of the late David Morgan, J.P., of Douglasleigh, Carnoustie, was born at Inverkeillor, Montrose, on December 2nd, 1871, and was educated at Aberdeen, where he graduated M.B., C.M. in 1893. Entering the R.A.M.C. as surgeon lieutenant on July 28th, 1894, he was promoted to lieutenant-colonel in the long war promotion list of March 1st, 1915, became colonel on December 26th, 1917, and retired on September 22nd, 1920. He was on special plague duty in Bombay in 1899-1921, when he received the thanks of the Government for his work. He served in the war of 1914-18 as A.D.M.S., and was mentioned in dispatches in the *London Gazette* of February 17th and June 22nd, 1915, January 1st, 1916, and May 29th, 1917. He received the C.M.G. in 1916, the C.B. on June 3rd, 1919, and the Legion of Honour. In 1918 he was a member of a British mission to Washington. Two years ago he was appointed honorary lieutenant-colonel of the Canadian Fusiliers and City of London Regiment. In 1905 he married Eleanor (O.B.E., 1919), daughter of the late T. H. Smallman of London, Ontario. By a curious mistake—a confusion with another officer of the same name and initials—his name was entered as dead in the casualty list in the War Office Army List for May, 1930.

Universities and Colleges

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-ON-TYNE

Centenary Celebrations

The one hundredth anniversary of the foundation of the University of Durham College of Medicine, Newcastle-on-Tyne, will be celebrated on Thursday and Friday, October 4th and 5th. During the afternoon of the first day the College will be open for inspection, and at 8.30 p.m. there will be an official reception of visitors by the President, Sir Thomas Oliver, in the Great Hall, followed by a conversation and dance. On Friday morning visits will be paid to view the clinical facilities of the College, the Department of Dentistry, and the Bacteriological Department and Public Health Laboratory.

In the afternoon there will be a luncheon party in the Great Hall of Durham Castle, and a special convocation in the Chapter House of Durham Cathedral, presided over by the Marquess of Londonderry, Chancellor of the University. Honorary degrees will be conferred as follows: Doctor of Civil Law, Sir E. Hilton Young, Minister of Health, and Sir Holburt Waring, President of the Royal College of Surgeons of England; Doctor of Hygiene, Sir Francis Dyke Acland, Chairman of the Dental Board of the United Kingdom, and Dame Janet Campbell, M.D.; Doctor of Surgery, Major-General J. A. Hartigan, D.G. Army Medical Services, Dr. J. W. Leech, M.P., and Dr. William Robinson; Master of Arts, Dr. W. D. Arnison. The closing event will be a commemorative service at 3 p.m. in Durham Cathedral, at which the Bishop of Durham, Visitor of the University, will give an address. *A Centenary History of the Medical School*, published by Andrew Reid and Co. Ltd. at 10s., has been prepared for the occasion by Professor G. Grey Turner and Dr. Arnison.

UNIVERSITY OF LONDON

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL

The following entrance scholarships have been awarded at King's College Hospital Medical School: *Raymond Gooch Scholarships*, D. I. Williams (King's College, London), S. C. Truelove (Trinity College, Hartford, Conn.), J. W. Yeo (Trinity College, Hartford, Conn.), C. I. Murphy (Queen's College, Oxford), R. B. Niven (Magdalen College, Oxford), *Epsom College Scholarship*, E. L. James (Jesus College, Oxford), *Seaman Scholarship*, J. Smallpeice (King's College, London).

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

DISSOLUTION OF PARTNERSHIP. II

QUARRELS BETWEEN PARTNERS

The court will dissolve a partnership in which so intense an ill-feeling has arisen between the partners as to destroy all their confidence in one another, or where there has been an irreparable breach, so that they can no longer carry on business together. A Master of the Rolls (Wray v. Hutchinson, 1834) once said that although the partnership would be dissolved if the defendant had substantially failed to perform his part of the agreement, yet it was not the duty of the court to consider mere partnership squabbles. Far too many cases are brought before the courts in which the disputing partners launch the most damaging charges against one another and seriously injure their own good names and that of their profession, besides ruining themselves financially. The court suppresses as much of this mutual abuse as it can, but has to hear such accusations as seem relevant to the applicant's case. The medical defence societies, the heads of the British Medical Association, the editors of medical journals, and all other men of authority in the profession are constantly advising medical partners to keep their quarrels out of the law courts, and I make no apology for emphatically repeating this advice.

Nothing does more harm to the profession or to a pair of practitioners than to have the evening papers full of their mutual and detailed accusations of fraud, sloth, chicanery, petty malice, drunkenness, and immorality. The files of this *Journal* and of the *Lancet* contain a number of instances of this disastrous form of litigation. The charges are nearly all much exaggerated by dislike and irritation, and even if they are true, why on earth have them published? It is the easiest thing in the world for two partners, however bitter their private quarrel may be, to take it to the secretary of one of the defence societies or of the British Medical Association, or to a solicitor with a large medico-legal practice, and have a legal agreement made to dissolve the partnership. If they cannot agree about the disposal of the goodwill and the partnership assets, any of these advisers can easily find them an able and experienced arbitrator of high standing whom they can both trust. They gain nothing by going to law, because when the dispute clearly arises from personal antagonism the judge will nearly always press the partners to settle their dispute out of court instead of wasting public time, and they will then find themselves constrained to appoint an arbitrator after all, having spent a large sum on legal advice and representation and gained nothing in return.

It is possible to multiply examples of this kind of litigation, but I will select one as typical of the general run of partnership squabbles.

Two medical men entered into partnership in London, one agreeing to pay £2,500 for a share in the other's practice. He paid up £2,000, but would not pay any more, and the other sued him for the balance. The purchaser counter-claimed for damages on the ground of fraud and misrepresentation, mainly as to the value of the practice; he also claimed the return of his £2,000 and the rescission of the partnership agreement. The seller thereupon accused the purchaser of chronic recurrent alcoholism, which made him incapable of constantly and regularly performing his part of the partnership agreement. After both doctors had wasted a great deal of time and money fighting the case, they yielded to the pressure of the judge and made a whole-hearted retraction of their statements.

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), the second on June 23rd (p. 1145), the third on July 7th (p. 42), and the fourth on July 21st (p. 141).

¹ *Lancet*, '926, ii, 37.

The partnership relation (remarks our contemporary) was evidently intolerable to both. Why could they not save themselves friction, cost, and publicity by a simple mutual agreement to dissolve? The purchase money was the stumbling-block, but if they could have referred the point to some umpire in whom both had confidence, he could have settled the dispute and they would not have needed to waste money in litigation.

If a partner finds himself in the unpleasant position of suspecting his fellow of serious misconduct, and decides that he must have recourse to a third party, he must take care that he does not expose himself to an action for libel or slander by his fellow. Even if he makes a statement to another person which he honestly considers necessary to protect his own and the partnership interests, he must be prepared to prove to the satisfaction of a jury: (1) that the third party to whom he resorted was one to whom he might rightly and reasonably have turned in the circumstances; and (2) that he acted in absolute good faith, with no ulterior motive. For instance, he may safely consult a solicitor, or ask in confidence the advice of another medical man of good standing whose wisdom and experience may help him and who has no personal prejudice, or approach a person with authority to take action. If, for instance, he considers it necessary to take the extreme step of having his partner certified as of unsound mind, he may furnish the necessary information to the medical man whom he is asking to give the certificate.

RIGHTS OF PARTNERS IN DISSOLUTION

When the court orders dissolution, the partnership will usually be dissolved from the date of the judgement. If, however, there has been any actual misconduct, or a breach of duty under the articles, or bad faith, the court may order the dissolution as from an earlier date, so that the guilty partner may not draw profits for the time during which the business was being damaged by his misconduct.

When a partnership is dissolved or a partner retires, any other partner may publicly notify the fact and require the other partners to concur in all necessary steps which he could not take without their consent, such as signing their names to an advertisement in the *London Gazette*—one of the means laid down by the Partnership Act of giving notice to all whom it may concern. The legal position of the partners, both with regard to each other and to outsiders, remains the same until the affairs of the partnership have been wound up and transactions which were commenced before the dissolution have been completed. Each partner, except a bankrupt, still has authority to bind the firm, and his rights and obligations are not altered. Each partner is entitled to have the property of the firm applied to pay off its debts and then to claim his share of the remainder, less anything he may owe the firm. For this purpose any partner or his representatives may after dissolution apply to the court to wind up the firm's business. A medical partner, however, cannot have the goodwill and connexion of the partnership sold, because its value is largely potential and depends on the future exertions of the several ex-partners.

In *Farr v. Pearce* (1818) A paid B a large premium for a share of his practice. A died and B sold the practice for a considerable sum. The representatives of A were held not to be entitled to any share of the money for which the goodwill was sold. Sir J. Leach, Vice-Chancellor, said in his judgement: "It would be difficult to maintain that where a partnership is formed between professional persons, as surgeons, and one dies, the other is obliged to give up his business and sell the connexion for the joint benefit of himself and the estate of his deceased partner. When such partnerships determine, unless there be stipulations to the contrary, each must be at liberty to continue his own exertions, and where the determination is by the death of one, the right of the survivor cannot be affected. Such partnerships are very different from commercial partnerships."

The goodwill therefore belongs to no one and is available to anyone who is willing and able to make use of it. When, however, goodwill has already been sold by some one in a position of trust, or under an arrangement made to defraud creditors, the court will order the proceeds to be paid to any person who has in conscience a right to them. For instance, a medical partner runs heavily into debt, and knows that in a month or two his largest creditor will make him bankrupt. He therefore assigns his interest in the practice in exchange for an annuity payable to his wife till her death and afterwards to him. The court would declare this transaction void as a fraud against the creditors.

RETURN OF PREMIUM

When one partner, on entering into partnership for a fixed term, has paid another partner a premium, and the partnership is dissolved—otherwise than by the death of a partner—before the expiration of the term, the court may order the recipient to repay as much of the premium as it thinks just, considering the terms of the contract and the length of time during which the partnership has continued. The court will, however, not order repayment if the partnership is dissolved largely because of the misconduct of the partner who paid the premium; or if it is dissolved by an agreement which contains no stipulation that any part of the premium should be repaid. The fraction to be repaid has always been determined by purely arithmetical means: dividing the whole amount of the premium by the number of years in the term and awarding the sum corresponding to the number of years that have elapsed. Death is excepted because it is a contingency that must be contemplated by everyone, and possibly lunacy may also be excepted. If an affluent partner pays a premium to a doctor whom he knows to be in financial difficulties, he may not be able to recover any of it if his partner goes bankrupt, but if he did not know that the recipient was embarrassed he may have the problematical satisfaction of proving his claim in bankruptcy. When a partner is seeking to recover some of his premium, counsel should ask for an order for its return at the trial of the application for dissolution. If this is not done, the partner will probably lose his money, for the court will only in special circumstances make an order after it has given judgement for dissolution.

The following cases illustrate the principles on which the courts order premium to be returned.

In *Freeland v. Stansfeld* (1854) two medical men, F and L, agreed to become partners for seven years. F paid L a premium of £900, and was to take one-third of the profits. In a year and a half L became bankrupt, and F sued S, the trustee in bankruptcy, asking for dissolution and the repayment out of the partnership assets of a proportion of the premium. S contended that F had had full value for his £900 in being introduced to L's patients and given the opportunity of forming a valuable connexion; he said also that if F had a claim he ought to make it as an ordinary creditor in bankruptcy. Stuart, Vice-Chancellor, declared in his judgement, however, that the premium was paid not for the introduction alone, but also in order that L should carry out his part of the agreement, which included the division of the profits. The partnership was ended prematurely by L's default, and as F could no longer obtain a considerable proportion of what he had paid for, it was not unnatural that he should claim that a corresponding proportion of his premium should be given back to him. It is a settled principle in equity that if, under a contract, a sum of money is paid for a consideration which afterwards fails, the recipient of the money must pay back that part of it which corresponds to the part of the consideration which has failed. The Vice-Chancellor awarded F £700 out of the partnership assets.

In *Astle v. Wright* (1856) the partnership was dissolved after a few months on account of personal friction. W, the newcomer, complained that A, the recipient of the premium, had failed to introduce him to the patients and had misrepresented the value of the practice. A, in his turn, charged W with neglecting to attend to the surgery, make up the medicines, or keep the books. Half the premium had been handed over; A claimed the remainder with interest and W claimed the return of what he had paid. The Master of the Rolls found that there had been no misrepresentation,

as W had spent a considerable time in A's house and had ample opportunity of judging the value of the business. He ordered A to return that part of the premium which corresponded to the unexpired term.

In *Atwood v. Maude* (1868) M, the recipient, alleged that A was so incompetent that the business could no longer be carried on, but the Court of Appeal considered that M had had ample opportunity to judge of A's capacity before he entered into the contract. As there had been no fraudulent or wilful misconduct, they ordered M to return an appropriate part of the premium.

In *Wilson v. Johnstone* (1873) Wickens, Vice-Chancellor, suggested that the court would only refuse to order the return of premium in a case where the payer had committed such deliberate and serious breach of the partnership contract as might be considered equivalent to a repudiation of it altogether. Mere conduct entitling the recipient to a decree for dissolution would not, he thought, be sufficient. The Act, on the other hand, lays down that there need be no return of premium when the dissolution is chiefly due to the misconduct of the payer, and return may perhaps be refused nowadays on grounds which would not have been sufficient before the Act.

It has been held more than once that, when the partnership articles contain a general clause providing a reference to arbitration of any difference between the partners as to anything relating to the partnership, the arbitrator can award dissolution and a return of premium (*Belfield v. Bourne*, 1894). It is, of course, always open to partners to agree to refer a dispute or conditions of dissolution to a named arbitrator and to abide by his finding.

FRAUD: CONTINUATION OF BUSINESS

If a partner is induced, by the fraud of another partner, to enter into a partnership and pay a premium, he has a choice of two remedies. He may either repudiate the contract altogether and sue for rescission, or he may affirm the contract and sue the offending partner for damages. If the other partner has misrepresented the value of the share or the nature of the practice, but not in such a way as actually to commit fraud, the aggrieved partner may successfully claim rescission and repayment.

When a partner proves that another has been guilty of fraud or misrepresentation and succeeds in obtaining an order of the court for the rescission of the partnership on those grounds, he is given several important rights in addition to his ordinary rights as a member of a dissolved partnership. He has a lien on, or a right to retain, the surplus of the partnership assets which is left over after the liabilities are settled, to satisfy him for any sum he has paid for a share in the partnership and for any capital he has contributed to it. If he has paid off any partnership debts, he may stand in the place of the creditors whom he has paid, and the partner who has committed the fraud or misrepresentation must indemnify him against all the debts and liabilities of the firm. He is treated, in fact, as though the partnership had never existed, and the law endeavours to place him, as far as it can, in the position which he occupied before he entered into the partnership agreement.

If a partner dies or otherwise ceases to be a partner, the partnership is, of course, dissolved. Nevertheless, it sometimes happens that the remaining partners carry on the business of the firm with its capital or assets. If they do this without settling a final account with the outgoing partner or his representative, then he or his representative is entitled either to that proportion of the profits made since the dissolution which the court may attribute to the use of his share of the partnership assets, or to interest at 5 per cent. on the amount of his share. When the partnership agreement contains a clause giving the continuing partners the option of buying the share of a partner who dies or goes out, and they exercise that option, then the outgoing partner or his representatives cannot claim any further profits. They must, however, comply in all material respects with the terms of the option, or they may have to account to him for his share of the profits since dissolution. The goodwill or connexion of the partnership is not an asset in this sense, but an appointment is.

Medical News

The annual dinner of past and present students of Charing Cross Hospital Medical School will take place on September 29th at the Café Royal, Regent Street, at 7.30 for 8 p.m., with Dr. J. Bright Banister in the chair; cost of tickets 10s. each. The autumn post-graduate course will be held on Saturday and Sunday, September 29th and 30th, from 10 a.m. to 5 p.m.

The new session of the London (Royal Free Hospital) School of Medicine for Women will open on Monday, October 1st, at 3 p.m., when an address on "The Institutes of Medicine" will be given by Dr. M. H. MacKeith, dean of the British Post-Graduate Medical School.

A post-graduate course, open to all medical practitioners without fee, will be held in the library of the new medical school, and in the lecture theatre of the Pathological Institute, at St. Mary's Hospital, on Friday, Saturday, and Sunday, September 28th, 29th, and 30th, commencing at 10.15 a.m. daily.

As already announced the annual old students' dinner of Westminster Hospital will be held on Saturday, September 29th, at the Trocadero Restaurant, at 7.15 for 7.45 p.m. The chairman on this occasion will be Mr. William Turner, senior surgeon, who retires from the active staff on October 1st, after thirty-seven years' association with the hospital.

A "refresher" course will be held at Middlesex Hospital Medical School from September 28th to October 1st inclusive at 10.15 a.m. daily. The course is open only to past students of the Middlesex Hospital. The opening ceremony of the new session will be held on Monday, October 1st, at 3 p.m., at the Queen's Hall, and the annual dinner at the Savoy Hotel at 7.30.

Two courses of lecture-demonstrations will be held at the Medical School, National Hospital, Queen Square, W.C., from October to December, 1934, and from January to March, 1935. These will include demonstrations on anatomy, physiology, and pathology, and demonstrations on post-mortem material, at 12 noon; lectures on the principles of neurology and on nervous diseases, at 3.30 p.m.; demonstrations of clinical methods of examination in nervous diseases, at 5 p.m. The autumn course of lectures from October 8th to December 7th, 1934, includes thirty-six lectures on the principles of neurology, and the winter course of lectures and demonstrations from January 28th to March 29th, 1935, includes thirty-six lectures on nervous diseases. The fee for each course is £10 10s., and special arrangements will be made for those unable to take the whole course.

The Fellowship of Medicine (1, Wimpole Street, W.1) announces that lecture-demonstrations will be given at 11, Chandos Street, W., on Tuesdays at 2.30 p.m., as follows: September 25th, paraplegia; October 2nd, tremor. Forthcoming arrangements include a week-end course in diseases of the heart and lungs at the Royal Chest Hospital, occupying the whole of October 13th and 14th; diseases of children at the Queen's Hospital, October 1st to 13th, all day; dermatology at St. John's Hospital, October 1st to 27th, afternoons and evening; physical medicine at St. John Clinic and Institute of Physical Medicine, October 1st to 27th, evenings; medicine and surgery at the Metropolitan Hospital, October 8th to 20th, all day; ophthalmology at the Royal Westminster Ophthalmic Hospital, October 15th to November 3rd, afternoons. Courses of instruction are open only to members and associates of the Fellowship.

The twenty-second annual conference of the Scottish Association of Insurance Committees will be held at Stranraer on September 28th and 29th in the Town Hall. The programme includes an address by Professor Charles McNeil, M.D., of Edinburgh.

The Royal Sanitary Institute has arranged a sessional meeting at Finchley on Friday, October 5th. At 3 p.m.

the members will inspect the Finchley open-air swimming pools in the Great North Road. The mayor will receive the members at 4 p.m. and entertain them to tea, and at 5 p.m., in the dance hall, papers will be read on "The Finchley Swimming Pools" by Mr. P. T. Harrison, and on "The Purification of Swimming Bath Water" by Dr. A. A. Turner.

The Minister of Health has had under consideration, in consultation with the Commissioners of Customs and Excise, what further steps can be adopted for avoiding conflicting decisions on the question of blindness for the purposes of (a) blind old age pensions under Section 1 of the Blind Persons Act, 1920, and (b) the registration of blind persons under schemes made by local authorities in pursuance of Section 2 of that Act. It has been decided that from October 1st next the pension officer, before reporting on a claim for a blind pension in England and Wales, shall send a form of inquiry (Form O.A.P. 87) to the appropriate registration authority asking the following questions: (1) Has the claimant applied for registration as a blind person? (2) Has the claimant been registered or refused registration? (3) In either case, was the claimant examined and certified by a medical practitioner with special experience in ophthalmology? (4) If the answer to (3) is in the negative, on what evidence was the claimant registered or refused registration? Where the Minister gives a decision on a pension appeal which is contrary to that previously given by the registration authority on the question of registration, he will on the request of the authority send it a copy of the medical certificate obtained by him.

The issue of *Paris Médical* for September 1st is devoted to ophthalmology and oto-rhino-laryngology.

Queen Marie of Yugoslavia will open the new Anglo-Yugoslav Children's Hospital at Kamenica this month. The hospital will specialize in the treatment of tuberculosis. According to Dr. Katherine Macphail, who founded the Anglo-Yugoslav Children's Hospital at Belgrade, where 170,000 patients have been treated, tuberculosis accounts for the death of 50,000 persons annually, and at any given time there are estimated to be more than half a million people suffering from the disease out of a population of rather more than thirteen millions. The Belgrade Hospital, which was for some years the only children's hospital in the country, has received support from the Save the Children Fund from its earliest years.

The King's Fund miniature hospital, built for King Edward's Hospital Fund for London at a cost to the contributing firms of nearly £3,500, has recently completed a year's successful tour of the provinces. The model is now to be exhibited at various leading stores in the London suburbs during the next few months.

Sir Grafton Elliott Smith of London and Professor Charles Nicolle of Tunis have been elected honorary foreign members of the Royal Academy of Medicine of Belgium.

Medical stamp collectors will be interested to know that the Hungarian Government has recently introduced stamps bearing the likeness of Philip Ignaz Semmelweis after the model of the French stamps with the head of Pasteur.

The Berne University Foundation for the Advancement of Researches on Encephalitis has offered a prize of 1,000 Swiss francs for the best work on the diagnosis and treatment of encephalitis. Competitors should communicate with the dean of the Faculty of Medicine of Berne.

The following appointments to professorial chairs have recently been made in the American faculties of medicine. Boston: Dr. W. Overholser, psychiatry; Dr. L. C. Howard, orthopaedic surgery and traumatology; Dr. D. Jacoby, dermatology; and Dr. L. W. Colburn, otology. Columbia University, New York: Dr. D. Symmers, general pathology; Dr. M. D. Rosenbluth, clinical medicine; Dr. C. Gordon Heyd, clinical surgery. Chicago: Dr. Amburger, clinical medicine. Harvard: Dr. S. H. Waite, ophthalmology.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisecra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 63550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Burning Sensation in Diabetes

"J. S. M." writes: I have a case of diabetes on insulin. This patient complains of an intense feeling of burning and heat over the lumbar regions. There is no sign of local irritation, and general treatment has failed to relieve. I would be grateful for suggestions as to cause and prevention. Can it be a specific effect of the insulin?

John Knight: Serjeant Surgeon

"E. M. C." asks for information about Dr. John Knight, Serjeant Surgeon in the time of Charles II.

* Sir D'Arcy Power wrote an article on "The Serjeant Surgeons of England and their Office." It appeared in *Janus* (1900, p. 174), and was reprinted in the *St. Bartholomew's Hospital Journal*, 1900-1, vol. viii, p. 81). Speaking of John Knight, who was appointed Serjeant Surgeon in 1661, he says: "He was one of those who attended Charles II on his voyage from the Hague to Dover at the time of his restoration. He was constantly occupied with matters concerning the sick and wounded seamen during the Dutch War." He was therefore mainly a naval surgeon, but as the two services were not then separate he also acted from time to time as surgeon general to the Army. Mr. Pepys dined with him, and reports him as being merry and very good company. Professor G. E. Gask has also written an account of the earliest surgeons attached to the Court in the *Proceedings of the Royal Society of Medicine* (vol. xix). Two further references to Serjeant Surgeons will be found in the *British Medical Journal* (1900, i, 583, and 1925, i, 224).

Head and Foot Presentation

Dr. PAUL GOLDSCHMIDT-FÜRSTNER (Cologne) writes in reply to Dr. Alastair C. Thomson's inquiry regarding the frequency or otherwise of simultaneous head and foot presentations (*Journal*, August 25th, p. 380): I found the following relevant passage in Jaschke-Pankow's *Lehrbuch der Geburtshilfe*, 1923—"Protrusion of a foot beyond or beside the head occurs practically only with an immature or macerated foetus, or it may occur in the case of twins, where both one replaces the foot, or if it has descended too far one changes the position into a true foot presentation through traction on the foot and replacing the head from without." Protrusion of both feet alongside the head is not noted. I myself have seen at least two cases in which one foot presented alongside the head, and in which reposition of the head with traction on the foot proved successful.

Income Tax

Employment Abroad

"J. A. F." entered into an agreement with a person residing in Canada to act as his medical attendant, and served him in that capacity abroad from September, 1931, to January, 1934. He had no residence in the United Kingdom, but paid short vacation visits here. Is the income liable to assessment?

* In our opinion, seeing that the services were rendered wholly abroad to a foreign principal, "J. A. F." is not liable. The contrary would, however, have been the case if he had maintained a residence here.

Division of Partnership Assessment

"E. C."—As for 1933, "A's" share was reduced from two-thirds and "B's" increased from one-third to one-half each. At the same time the profits of the practice fell from £4x to £3x. Consequently "B" is now assessed at one-half of £4x, whereas he did not receive more than one-half of £3x. Has he any remedy?

* No. There has been no change in the personnel of the firm, and consequently a fresh start cannot be claimed for the operation of the basis of assessment of the previous year. It is a result of the principle of dealing for income tax purposes with a firm as a distinct entity, and a fluctuation (up or down) of profits necessarily disturbs the equity as between the two partners.

Payment of Subscriptions

"J. C." refers to an issue of this *Journal* in which it was stated that subscriptions to the British Medical Association, medical defence societies, etc., were deductible, and explains that in his income tax return, made as an assistant M.O.H., he claimed to make such deductions, and his claim was refused.

* The reply to which our correspondent refers related to an assessment under Schedule D in respect of profits, whereas his personal liability falls under Schedule E as being in respect of the emoluments of an employment. There is an unfortunate difference, the statute being stricter in the case of Schedule E. The point was decided against the taxpayer in 1925 in the case of *Simpson v. Tate*.

LETTERS, NOTES, ETC.

Asthma in Children

Dr. ALEXANDER FRANCIS (London, W.) writes: The letters by Sir James Dundas-Grant in the *Journal* of August 4th and by Dr. James Adam in the issue of August 18th on asthma in children are valuable in drawing attention to the importance of nasal examination, and to the necessity of putting some check upon the present craze of considering allergy as the root of all ills. It is really amusing to note how apt we are to run any new idea to death. Allergy, sinusitis, septic tonsils, adenoids, intestinal sepsis, etc., are active sources of irritation, but they are only the exciting causes of asthma. Certainly it is important to remove such irritations, but we must not allow them to mask the fact that the fundamental cause of asthma is vasomotor instability. I could quote case after case in which vaccines and immunizing injections against allergic irritants have proved useless, and in which such irritants have lost their harmful effects when the vasomotor system has been made stable. In one case a boy of 12½ had had twenty-five months of weekly injections, in addition to having had his tonsils, adenoids, and appendix removed, and to undergoing two years of glucose treatment, without deriving any apparent benefit. As soon as his vasomotor system had been made stable and he was fitted with proper glasses his asthma left him. Another boy of 14, who had suffered from asthma from the age of 3, had had five years of injections in the vain hope of immunizing him against the supposed allergic causes of his trouble. He obtained almost immediate relief after I saw him in 1932, and has remained free from asthma, except for occasional attacks as the result of some undue excitement. Owing to the fact that the nervous system in children is more impressionable than in adults, it takes a rather longer time as a rule to make their vasomotor systems stable, but as a class they give a higher percentage of good results.

Prognosis in Hypertension

Dr. H. O. GUNewardene (Colombo, Ceylon) writes: It is very interesting to read Dr. Platt's observations upon hypertension and albuminuria in the *Journal* of July 21st (p. 138). For many years I have found that a persistent diastolic pressure of 130 or over, and a urine showing what I have chosen to describe as a "cigarette-puff density" of albuminuria to the heat test, is reliable ground on which to base a very bad prognosis, even in the absence of serious changes in the retina. I have used this expression as regards the albuminuria in order to indicate in a simple way that the quantity of albumin need not be much. It may be anything above this quantity. Here is an illustrative case:

M. R. C., aged 39, married, seen by a doctor, sought advice as he was rejected by an insurance company, being a case with high blood pressure. Condition on examination: Apex beat, quarter of an inch external to nipple line; pulse 72; blood pressure 200/140; lungs normal; spleen ++ (malarial); liver normal; urine, specific gravity 1005, albumin +, no sugar. Micturition was twice nightly and four to five times a day. There were no arterial changes in the fundi. Treatment was by (1) lacto-vegetarian diet, with weekly fasts; (2) elixir sodium sulphocyanate (P. D. and Co.), as directed; and (3) potassium iodide, potassium bromide, and magnesium sulphates. This patient died within nine months from cerebral haemorrhage.

These two observations seem to be quite enough in most cases, whatever the pathology of the kidney. When a patient comes with a single specimen to the general practitioner's consulting room, or even to a specialist, one is often obliged to give a prognosis if possible without the help of so many renal function tests—at least when the patients cannot afford to pay the biochemist or are unwilling to attend hospital.

Treatment of Dysmenorrhoea in Virgins

Dr. NUTTING FRASER (St. John's, Newfoundland) writes: In the *Journal* of August 11th (p. 257) you review Dr. James Young's *Text-book of Gynaecology* in a very favourable way, expressing views which those of us who have read the book will heartily endorse. You do not agree with him that "an infected cervix is a common cause of pain in women," and I would like to state that my experience quite coincides with the opinion expressed in Dr. Young's book. I find that many of the cases of severe dysmenorrhoea in young girls are caused by an infected cervix, and medicine is powerless to relieve the distress. Of course, we all hesitate to examine a virgin, and such examination calls for a general anaesthetic. But if the small rectal speculum, commonly used for injecting haemorrhoids, is used, an examination can be satisfactorily made without any injury to the hymen. The cervix can be exposed, drawn down, and cauterized. Five years ago a lady asked me to treat her maid for dysmenorrhoea, the pain being so severe that she lost a couple of days each month. Medicine proved ineffectual, but the patient was desperate, and would submit to anything that might give relief. An examination was thus decided upon and was made under an anaesthetic. The cervix was badly eroded and exuded pus. Both lips were deeply cauterized, and up to the present time the result has been a complete relief of the pain. Menstruation is regular and painless. Following this case I have treated many others in the same way, and always successfully, and I would like to draw attention to the fact that the rectal speculum can be used like the old Ferguson speculum, and need not damage the hymen.

Adrenaline and Cerebral Haemorrhage

Dr. A. J. DUNLEVY (Ogmore Vale, Glamorgan) writes: The history of this case may prove of sufficient interest for publication. I must state that the treatment was accidental, but I think the case worth recording as an observation. Whilst acting as locumtenent I was called to see a woman who was supposed to have swallowed some liniment in mistake for brandy. She certainly may have tasted the liniment, but she had not swallowed any. I gave the usual milk and albumin treatment, and satisfied myself that she was all right before I left her. I was called to the same patient that afternoon and found her unconscious, with stertorous breathing. I had been told by her own doctor that this patient had a bad heart. Without waiting to do any examination I gave 1/100 grain adrenaline and 1/30 strychnine. After I had given the injections I discovered that there was a hemiplegia of the left side, and that the case was really one of cerebral haemorrhage. I felt that I had made a grave error in treatment. I saw the patient later that night and found her a little better. Next morning she was conscious, and felt quite well; in fact, it was with difficulty that she was persuaded to stay in bed, as she felt so fit. I think the original "poison" fright probably caused the cerebral haemorrhage. We know that

adrenaline constricts the vaso-constrictor nerves, but I think that it is generally understood that the cerebral vessels are not supplied with vaso-constrictor nerves. Hitherto, I thought that adrenaline would have been contraindicated owing to the danger of the raised blood pressure driving more blood into the ruptured lenticular striate branch of the middle cerebral artery. In this case I used adrenaline accidentally, and I wonder if the raised blood pressure retarded the haemorrhage by slowing the rate of extravasation (Marie's law); the constriction of the aorta and large blood vessels serving also to reduce the haemorrhage. The case may interest your readers, as, personally, I am convinced that adrenaline is well worth trying in these cases, which are so often left to nature to cure.

Labour and Heart Disease

Dr. CHARLES J. HILL AITKEN (Kilnhurst, near Rotherham) writes: In connexion with two *Epitome* paragraphs dealing with the above subject (No. 131, August 18th, and No. 150, August 25th) I read in the late D. Berry Hart's *Midwifery* the following statement: "I early advocated the view, which has also been brought forward by Dr. Angus MacDonald and others, that the serious results in the third stage were due to an embarrassment of the right side of the heart . . . and that thus the best thing for the patient was not to hinder loss of blood in the third stage, but rather to see that the patient lost blood to a fair amount, and that if there were any doubt of this she should be bled from the arm" (p. 337). This was written in 1912, and Dr. Angus MacDonald died a great many years ago.

Medical Work in Basutoland

Dr. N. M. MACFARLANE, late principal medical officer in Basutoland, has compiled a record of medical work in this Territory. It is of special interest at the present time when there is a general movement to develop health services for native populations, for it shows how one small native State proceeded. The Territory of 11,000 square miles is populated by over half a million natives. Dr. Macfarlane describes the early work of the missionaries, who were solely responsible for scientific medicine until the appointment of the first Government medical officer in 1875. Details are given of the energetic pioneer work of the early officers, Drs. E. B. Hartley, H. S. Taylor, L. C. Daumas, and S. C. Reed. Small hospitals and free dispensaries came into being, and in the last decade of last century the medical work was growing apace. The South African War brought further expansion; the existing small hospital at Maseru was enlarged and modernized, and new ones were opened elsewhere. One achievement of this period was the almost complete eradication of small-pox, which had previously been endemic for many years. More than half a million vaccinations had been performed, and it had been made compulsory for all natives leaving the Territory to carry a vaccination certificate signed by a medical officer. The first leprosy asylum was established by one of the enlightened native chiefs, and this led the way to the opening of the Basutoland asylum in 1913. The usual difficulties followed its being conducted more as a house of detention than as a hospital. Despite the difficulty of financing a rapidly growing medical service, progress continued; sanitary areas were defined, and more medical officers of districts were appointed by the Government. Active work against leprosy continued, and paved the way for the complete survey some four or five years ago. The leprosy organization was inevitably planned on a rather expensive basis, its inception having preceded the more recent discoveries which have led to great economies.

A Schedule to the "National Formulary"

The Paddington Medical Society has issued a revised edition of their *Schedule to the National Formulary*, which shows the approximate and the relative cost of the formulac and of the dispensing fees in the *National Formulary* (1933). Copies can be obtained (price 1s.) on application to the honorary secretary, Paddington Medical Society, 81, Elgin Avenue, London, W.9.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 38, 39, 40, 41, and 44 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 172.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, SEPTEMBER 29th, 1934

THE VALUE OF ANTISEPTICS IN THE CONTROL OF BACTERIAL INFECTIONS*

BY

C. H. BROWNING, M.D., F.R.S.

GARDINER PROFESSOR OF BACTERIOLOGY, UNIVERSITY OF GLASGOW

The question, How far can infections by pathogenic organisms be influenced for the benefit of the host by means of antiseptics? incidentally involves inquiry into the properties of antiseptics which suit them for such purposes, and also into the methods of their application. By "antiseptic" is understood a substance of ascertained chemical constitution harmful to the activities of micro-organisms. The problem, then, is one of chemotherapy in the sense defined by Ehrlich. Restricting consideration to the ordinary bacteria, we shall see that success has been chiefly obtained where the drug can be brought into close contact with the site of a localized infection in a wound or natural cavity. Therefore the chemotherapy of bacterial infections is at present most intimately associated with surgery. Generalized bacterial infections are still practically beyond the reach of antiseptics. This admission must not be interpreted as the confession of failure: the antiseptics now available have very great therapeutic potentialities, and the advances already made open up still wider prospects. It must be remembered, too, that until recently little has been done to correlate biological and chemical work on the problems. In order to clarify the present position the scientific origin of antiseptic treatment will be traced, and the limitations of the older antiseptics will be noted.

Lister and Antiseptic Therapy

Lister was without doubt the first to employ antiseptics on a scientific basis. Fortunately, his guiding principles are authoritatively summarized by the late Sir Hector Cameron in the Dr. James Watson Memorial Lectures (1907), which had been submitted for revision to Lister himself.

"It was hard, perhaps, to appreciate the fact that carbolic acid was not used by Lister (as it undoubtedly had been previously used by others) as 'a local dressing of wounds' with the view of acting directly, and with a specific healing influence, on the wounded tissues, but rather that it was employed to destroy germs which, if they reached the wound in the living state, had the power of preventing the natural processes of repair. . . . His constant aim was to place wounds, as far as possible, in conditions resembling those of subcutaneous injuries, free from the access of external morbid agencies, as well as from direct irritation by foreign substances."

Lister, it is true, applied carbolic acid to the soiled tissues exposed in a compound fracture for the express purpose of destroying pathogenic bacteria which had

obtained access to the living body. He must therefore be considered the scientific pioneer in this form of therapy. It should be borne in mind, however, that his attitude was obviously that of one who unwillingly employed an extreme measure to meet a desperate situation. In addition, he was aware of the uncertain efficacy of carbolic acid when used for this purpose, since he observes: "while we endeavour to purify the wound with strong carbolic lotion we cannot be certain of entire success."† The harmful action of carbolic acid on living tissues appears to have been well known to Lister; he did not contemplate its introduction into the abdominal cavity because "it must be in itself a very desirable thing to avoid the direct application to the peritoneum of strong and irritating antiseptic solutions." Further, as Sir Hector Cameron says:

"When dealing with abscess, no antiseptic was ever introduced into the cavity at all. It was far otherwise with many of those who counted themselves amongst his disciples and imitators. Not perhaps thoroughly appreciating the scientific facts which were the basis of the treatment, they were unable to divest themselves of the old idea, that, whatever was used in the treatment of a wound, was necessarily intended to have some specific effect on its healing. It could not, therefore, be brought too freely or too often into contact with it. They filled kettles with carbolic solutions, and poured them over wounded surfaces or injected these same solutions into all interstices of wounds with syringes, while abscesses, empyemata and the like were freely syringed out in the same manner at the time of operation, as well as at every subsequent dressing."

The other antiseptics contemporaneous with carbolic acid—namely, the perchloride and other salts of mercury, boric acid, iodoform, and iodine, etc.—all suffered from the same disadvantage that if employed in concentrations sufficient to damage bacteria their general effects as "protoplasm poisons" on the tissues of the host tended to become prominent. Now it must be remembered that Lister's condemnation of the application of antiseptics to the tissues referred to those substances of which he himself had experience. I am not aware that he ever denied the possibility of finding antiseptics suitable for this purpose.

Need for Therapeutic Antiseptics

The result of Lister's teaching was that operations of election were regularly performed without the super-vention of wound infections. This safe conduct into the texture of the body was the prerequisite of the miracles

* Read in opening a discussion in the Section of Pathology, Bacteriology, and Biochemistry at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

† In view of this uncertainty, Lister in such cases came to employ in addition iodoform, which he regarded as probably acting not directly on the bacteria, but by inducing chemical changes in their toxic products as suggested by Behring.

of modern operative surgery. No blessing, however, seems altogether unmixed, and the fact that aseptic wounds can be inflicted at will with so great a measure of confidence has led to undesired consequences which in all probability were entirely unforeseen.

First, the occurrence of infection in a wound of election has now commonly come to be regarded as due solely to some fault in the preparations for, or in the performance of, the operation. In order to realize the error of this generalization one need only recall the "cryptogenic" infections with pyogenic bacteria in deep tissues altogether apart from any gross trauma. Even gas gangrene sometimes arises at a site remote from the point of entry of the organisms (see Learmonth, 1924). If bacteria can settle, multiply, and set up a focus of disease at a site without any preceding bruise or other gross local pathological condition, it is clear that they are even more likely to behave in this way where the tissues have been damaged by the surgeon's knife. A wound, even when inflicted under the strictest aseptic conditions, constitutes a site of lowered resistance, and is therefore liable to the lodgement of organisms which may reach it from the blood or lymph streams. Consequently, there is certain to be a proportion of septic accidents following operations of election which are due to infection acquired from within, and which cannot be avoided by a technique which aims merely at hindering access of bacteria from that surface whose continuity is breached by the surgeon. Here there is obvious need for a tissue antiseptic. Omission to guard against such endogenous infections must be due to a mistaken interpretation of Lister's teaching.

Again, where the operator is compelled to approach his objective through a naturally infected surface, such as the conjunctiva or a mucous membrane, strong solutions of the old antiseptics cannot be used, unless, of course, a diffuse caustic effect is desired. It is perhaps on this account that the occasional occurrence of meningitis after operative procedures on the nose and related cavities is sometimes viewed as an inevitable accident. Another undesired consequence has been a failure of interest in improving methods of treating wounds which are already infected before coming under the surgeon's care, probably because a feeling of responsibility for such infections has been wanting. The attitude reflected in many surgical textbooks to-day is that in the treatment of infected tissues it matters little what antiseptic is used, since its function is quite subsidiary to that of appropriate surgical manipulation—in other words, excision, drainage, and the natural defensive powers of the tissues will do all that can be expected.

Thus, after the pioneer work of Lister and Koch, therapeutic investigation of antiseptics did not advance rapidly. Behring, Koch, and Stilling pointed out the powerful antiseptic action of certain basic aniline dyes, and Stilling (1891) recommended methyl-violet for treating infections of the conjunctiva and joints. Also extremely potent new organic antiseptics were described by Bechhold and Ehrlich (1906). But these researches attracted little attention.

Stimulated by Ehrlich's fundamental work on the chemotherapy of protozoal diseases, and by observations made by Churchman and Dreyer, Kriegler and Walker on the properties of methyl (gentian) violet, Browning and Gilmour (1913) studied more thoroughly relations between chemical constitution and antiseptic action among the organic dyes, including several of the acridine series. Two of the latter, proflavine (3:6 diamino-acridine) and trypaflavine (acriflavine) were put at our disposal by Ehrlich; the last was also examined independently by Shiga for antiseptic action on *V. cholerae*. The need for improving the treatment of war wounds led

to renewed activity, and subsequently many substances have come into use; a number of these are a great advance on the older types of antiseptics as therapeutic agents. It is impossible to deal with them all in detail here, but I shall review the experimental evidence of the efficacy of antiseptic treatment and indicate briefly the clinical bearing of the facts.*

Antiseptic Therapy of Recent Infections in Wounds, Serous Cavities, etc.

In order to obtain decisive evidence regarding the curative action of antiseptics it was necessary to make controlled observations on animals. Various organisms and methods of inoculation have been used. As regards imitating pyogenic infections of man, a difficulty is the tendency for the infections in laboratory animals to become quickly generalized.

However, an infection of recent skin wounds in guinea-pigs with a culture of virulent *B. diphtheriae* affords a very suitable test object for therapeutic agents (Feiler). The bacilli do not become generalized, so that in this important respect the condition resembles that usual in human wounds contaminated with pyogenic organisms. At the same time conclusive proof of the effect of treatment is obtained, since in the untreated controls death occurs in forty-eight to seventy-two hours. The following procedure was adopted (Browning and Gulbransen, 1925).

Experimental Technique.—When the animals were under the influence of a general anaesthetic two parallel linear cuts, each about $\frac{3}{4}$ inch long and $\frac{1}{3}$ inch apart, were made in the shaved skin of the abdomen in the long axis of the body. The strip of skin between the cuts was raised from the deeper structures, and also that for about $\frac{2}{5}$ inch on either side of the incisions, so as to form pockets, there being practically no bleeding, and a quarter of a young, well-grown agar culture of virulent *B. diphtheriae* was rubbed into the wounds and the pockets. Periods of $\frac{3}{4}$ to two hours were then allowed to elapse before treatment. This consisted in washing out the wounds with 1 c.cm. of a water solution of the substance under test, and swabbing the pockets with a small pledget of cotton-wool which had been soaked for several minutes beforehand in the same solution. The animal was placed on its back during treatment, and the whole procedure lasted for seventy-five seconds. Finally, any fluid not absorbed by the tissues was allowed to drain away and the surrounding skin swabbed dry. There was no further treatment, and all survivors were kept for at least three weeks.

Results.—The outcome of the above experiments was that out of twenty-two inoculated animals treated with acriflavine (1 in 100 to 1 in 2,500) twenty-one survived, whereas of seven treated with carbolic acid (1 in 20 to 1 in 100) five died, and of fourteen whose wounds were washed out with either 0.85 or 5 per cent. salt solution all died. Iodoform in the form of "bipp," rubbed into the infected wounds, failed to save the life of all three animals so treated. Acriflavine is about fifty times more potent than carbolic acid, as measured by the concentrations of the two substances required to bring about cure. Further, it has been shown that the curative effect of acriflavine is not caused by destruction of diphtheria toxin present in the culture used for inoculation, but is due to action on the bacilli (Braun).

Other Investigations.—Virulent streptococci, either in the form of cultures or of material (blood, etc.) from infected animals, have also been used to inoculate recent skin wounds in mice (Reinhardt, Schiemann and Wreschner, Weise, Collier and Bernhagen). In such experiments failure of the therapeutic agent is shown by the animals dying of septicaemia. Here also a single brief application of one of the new antiseptics half to one hour or later after

* Bennett, Blacklock, and Browning (1922) give a critical discussion of earlier clinical observations.

inoculation has preserved the animals from an otherwise fatal infection. It is noteworthy that Weise found excision of the surface of the wound one-quarter to two hours after inoculation to be without beneficial effect. When the inoculation was made into deep wounds of muscles, treatment was less effective than in more superficial wounds. Reinhardt obtained similar results with recent skin wounds in guinea-pigs inoculated with pneumococci and treated by washing of the wounds with the antiseptic half an hour later. The most effective of a series of substances tested was acriflavine; on the other hand, 1 in 20 carbolic acid and tincture of iodine were without perceptible action, but mercuric chloride 1 in 1,000 prolonged the life of the animals. The controls, whose wounds were washed out with saline, died in two to seven days. Infection of the cornea in rabbits, produced by injecting virulent pneumococci, has been sterilized by optoquine instilled into the conjunctival sac or injected subconjunctivally (Ginsberg and Kaufmann). In guinea-pigs inoculated intramuscularly with soil containing pathogenic anaerobes of the gas gangrene group and *B. tetani*, Brunner, Gonzenbach, and Ritter (1918, 1924) showed that the resulting fatal infection could be prevented by antiseptic treatment, even when begun many hours afterwards. All organisms are not equally susceptible in the tissues, however. Thus, Hata (1932) failed to influence recent wound infections with *B. oedematis*, although this bacillus was not specially resistant to the antiseptic *in vitro*, and the acridine compound which he used was effective against other organisms *in vivo*. The troublesome local septic infections of the skin which tend to occur in scarlet fever patients, owing to contamination with discharges from the nose or ear, have been regularly prevented by treatment of the latter with acriflavine (J. W. Howie, unpublished). It should be noted that in the experiments on wound infections referred to above, the physical conditions were the same in the treated animals and the controls. This is very important, since, as Preobajensky showed, an alteration in the physical conditions of an infected wound may of itself determine the outcome of the infection.

Peritoneal Inoculation.—Where the inoculum is introduced into the peritoneum, from which generalization rapidly occurs, the therapeutic problem is obviously difficult. Nevertheless, very considerable success has been obtained in mice infected with virulent streptococci and treated after an interval, usually one hour, by an intraperitoneal injection of a suitable antiseptic. Untreated controls, or those which received only physiological saline intraperitoneally, died from septicaemia in twenty-four to forty-eight hours. The following results were obtained with the most effective substances tested by Browning, Cohen, Ellingworth, and Gulbransen (1931).

Therapeutic Agent	Cures Treated
2 (p-dimethylamino anil) (2 to 3 of tolerated dose used) ...	34 out of 47
6-methylallyl-acetyl amino-quinoline methochloride	Together 87 cures out of 129 treated
2 (p-dimethylamino anil) (2 to 3 of tolerated dose used) ...	
6-n-propylamino-quinoline methochloride	53 out of 82
Acriflavine ...	13 out of 21
(2 to 3 of tolerated dose used)	

Untreated controls: Of 125 animals inoculated all died in 24 to 48 hours.

Many other substances were without effect, including carbolic acid 1 in 300 (the largest tolerated dose). The general result also of similar experiments by others is that an appropriate antiseptic cures an infection which without it will develop into a fatal septicaemia. The objection may be raised that the interval between inoculation and treatment is short, but in small animals the infection progresses rapidly, so that the period is a considerable fraction of the whole illness.

Treatment of Local Suppurative Processes

Such lesions are not easily produced experimentally in laboratory animals, there being, as a rule, a marked tendency for the infection to spread. Morgenroth and his co-workers tested the effect of the local injection of antiseptic in sterilizing the tissues and preventing the development of a "phlegmon" in mice after subcutaneous inoculation with pyogenic streptococci. But the results tend to be irregular, owing largely to the uncontrollable factor of the individual animal (Browning and Gulbransen, 1928). In experimental empyema in the rabbit, produced by inoculating one pleural sac with streptococci, Gay and Morrison, on injecting acriflavine into one or both pleurae, and in some cases also aspirating the exudate, did not succeed in saving the life of the animals. Although the pleural contents were sometimes nearly sterilized, regrowth and spread of the organisms occurred. Eggerth, employing similarly a mixture of proflavine and sodium oleate with the same object, obtained more promising local results; but here again generalization of the infection vitiated the effects of the treatment.

Observations on treatment of the human subject are seldom adequately controllable, but when in one individual separate lesions, similar in size, severity, and situation, are treated by different methods, differences in the results can justifiably be attributed to the treatment. Graham's (1925) case is convincing in this respect. Three areas on the back of the hand and forearm in which the whole depth of the epithelium had been destroyed by contact with boiling fat, were dressed with acriflavine (1 in 1,000) within an hour after the injury. Two days later granulation tissue was present in the base of all the burns, and there was no suppuration and little discomfort. Then on one of the areas a dressing of wet boric lint was substituted, while the others continued to be treated with acriflavine (1 in 5,000), each dressing being renewed once daily. After six days' application of boric acid the area so treated was actively suppurating and extremely painful, whereas the others were free from sepsis and showed healing in progress. Accordingly, boric acid was replaced by acriflavine, and after three days further this area also was free from pain and suppuration. The results of Turner (1919) in septic and fetid conditions of the gums also have the decisive character of an experiment. In cases where the bad odour was readily detected at several yards' distance from the patient, the breath, twenty-four hours after commencing treatment with acriflavine, was free from smell.

Infections of the urinary tract may be considered here, since local application of the antiseptic can be secured either from beneath by injection, or from above by administering by mouth or intravenously substances which are excreted in the urine. The observations are almost wholly clinical, and, as regards the second method, the substances usually employed are so feeble in their action that doubts regarding their efficacy are not surprising. Infections of the kidney, whether a gross obstruction such as a calculus in the pelvis or ureter be present or not, probably cannot be sterilized by any urinary antiseptic at present available. It is possible, however, in healthy men to procure unfailingly the secretion of urine antiseptic toward both *B. coli* and staphylococcus after the administration of acriflavine combined with alkalization* (Davis and Sharpe). This fact does not appear, however, to have been much utilized—for example, as a measure preparatory to operation on the urinary tract. The value of antiseptics in the therapy of gonorrhoea at an early stage seems not to be doubted, but much more work is required to discover an ideal treatment.

* A difficulty is the tendency towards nausea and catharsis

The secretion of antiseptic bile is still to be achieved. Intrathecal antiseptic medication in meningitis has not been shown definitely to yield favourable results. It appears so far impossible to influence the bacterial flora of the alimentary tract by antiseptics (Garrod, 1926; Graham, 1932; Browning, 1933).

General Infections

Koch originally attempted to treat septicaemia by an antiseptic. Mercuric chloride being highly inimical to *B. anthracis*, he injected guinea-pigs repeatedly with it both before and after inoculation with the bacilli. The animals, however, died like the untreated controls, in spite of having received in proportion to their weight an amount of the mercury salt sufficient to prevent all growth of the organisms in a broth culture. Morgenroth and Levy cured experimental pneumococcus septicaemia in mice by optoquine. With this outstanding exception, all attempts to cure a general bacterial infection by such means have failed under experimental conditions, although the bactericidal powers of the blood or serum may be raised temporarily by the injection of certain antiseptics. In experiments already mentioned recent streptococcal infections of the peritoneum were cured by an intraperitoneal injection of antiseptic when organisms were already present in the blood of a control animal. This, however, may merely mean that a certain degree of bacteraemia does not preclude cure provided that the chief source of infection can be effectively dealt with.

Properties of Therapeutic Antiseptics and their Mode of Action

The new therapeutic antiseptics are mostly dyes. This property is objectionable to many, and doubtless when more is known regarding relations of chemical constitution to antiseptic action colourless substances fitted for the purpose will become available. Further advance depends chiefly on the synthesis of still more suitable compounds. It is important, therefore, to define as far as possible those characters of an antiseptic which indicate its therapeutic value. The essential property, of course, is that the harmful action on bacteria shall exceed that on the tissues.

Effect on Bacteria.—Rapidity of bactericidal action is not essential. Organisms, although continuing to be viable, may nevertheless be profoundly altered in their pathogenic action by contact with the antiseptic, so that the natural defensive mechanisms of the host can come into play effectively. Accordingly, favourable therapeutic results are likely to be due as a rule to co-operation between the drug and the tissues. As an example of this, a concentration of antiseptic sufficient to cure a recent peritoneal infection with streptococci, or to prevent infection when injected as a mixture with the organisms, has been found to take some hours to kill the cocci *in vitro* (Browning, Cohen, Ellingworth, and Gulbransen, 1931).

The following observation illustrates well this problem of reducing virulence (J. W. Howie, unpublished). A strain of streptococci of which a two-thousand-millionth of a cubic centimetre of fluid culture injected intraperitoneally regularly killed a mouse, was treated with acriflavine in gradually increasing concentrations *in vitro*; finally, although the organisms still grew vigorously, the injection of 1/2 c.cm. of the undiluted culture was harmless.

Again, selective action on one species of bacteria as compared with another may have to be reckoned with, so that the nature of the infecting organism may decide what antiseptic is to be used. However, many of the new antiseptics—for example, acriflavine, proflavine, rivanol, quinamil (Armitage and Gordon), and mercurochrome-220, as well as brilliant-green—all act fairly uniformly on

various common pyogenic organisms, although *B. pyocyaneus* tends to be resistant to many. A valuable character of certain of the new antiseptics is that their powerful action on bacteria is not reduced by serum. Substances such as mercury compounds and chlorine derivatives do not merely suffer dilution by serum, but their antibacterial property is enormously weaker in serum than in a watery medium. Among substances not inactivated by serum are acriflavine, proflavine, rivanol, quinamil, and many other analogous compounds prepared by Professor J. B. Cohen and his co-workers. When inactivation by serum occurs frequent renewal of the antiseptic is necessary.

Mutual Effects of Tissues and Antiseptics.—Several effects must be considered. Fixation and consequent inactivation of the antiseptic by tissues and pus occurs to some extent probably with all antiseptics. Graham (1928) measured the absorption of acriflavine, carbolic acid, and mercuric chloride by minced muscle soaked in solutions of these drugs. Mercuric chloride is powerfully fixed, the other two less so; on the other hand, acriflavine alone of the three is fixed by cotton, and this must be allowed for when applying wet dressings, otherwise one may merely treat the wound with dyed cotton instead of antiseptic solution. It is possible that fixation of the antiseptic by the tissues in an infected area may sometimes be advantageous, since in this way a depot may be created from which continuous action on the organisms will be maintained. Morgenroth attributed the greater therapeutic effect of one substance as compared with another on streptococci in the subcutaneous tissue to such differences in fixation, although both were equally antiseptic *in vitro*.

The liability of tissues to injury from an antiseptic may be measured in various ways. Thus, intravenous injection shows the action on the animal as a whole or on any specially susceptible organ. Unless a substance is intended for intravenous administration, however, this test of toxicity may be too exacting, because a substance like brilliant-green, which is very toxic intravenously, is tolerated safely when applied to the open surface of a wound. Subcutaneous or intramuscular injection also indicates general toxicity provided absorption takes place; these methods, further, show the local action on tissues. But here again the effect of introducing the substance into the closed tissues may differ from that in an open wound; for example, brilliant-green solution subcutaneously in the rabbit causes marked persistent local oedema, but when used to dress a wound does not have this effect. Action on delicate surfaces may be ascertained by instilling a solution into the conjunctiva of an animal and retaining it there for some minutes, or by injecting it into the peritoneum.

In all such tests the varying behaviour of different species and even of different individuals must be considered. It is important to avoid irritation of delicate surfaces which harbour bacteria; thus antiseptics applied in a concentration sufficient to irritate the nasal passages in rabbits led to lighting up of latent pasteurella infection. A number of the new antiseptics are distinguished by the relatively high concentrations required to cause marked irritation or damage of the tissues as compared with the low concentrations which harm bacteria. Tests on cells *in vitro* have been proposed; the difficulty is to relate them to conditions *in vivo*. Some observers have concluded from such experiments that the tissues are always more vulnerable than the bacteria, and so antiseptic treatment has been condemned by analogy. In actual fact, as has already been seen, infections which would otherwise be certainly fatal can be cured by antiseptic chemotherapy. The method of tissue culture has also been utilized, whereby bacteria and fragments of embryonic tissue are

incubated together for twenty-four hours in a nutrient fluid containing the antiseptic. In this way the concentration of the drug inhibiting proliferation of the fibroblasts and that preventing growth of the bacteria can be ascertained. Of all substances tested, including carbolic acid and mercuric chloride, the only ones which inhibit streptococci in a concentration lower than that damaging to the tissue are acriflavine and other acridine and quinoline compounds (Mueller, Hata). According to Hata, trypaflavine (acriflavine), rivanol, and certain new acridine compounds permit proliferation of the tissue cells in a concentration several times greater than will prevent growth of streptococci. The significance of these results cannot be disregarded, since conditions *in vitro* are much more favourable for the bacteria than for tissue cells. On the other hand, we do not know the relative vulnerability of the fibroblasts of chicken embryos and the mesoblastic elements of adult human and other mammalian tissues. A highly desirable action of an antiseptic would be to penetrate cells without harming them and to inflict damage on organisms in their interior; probably this does not occur. Failure also to act on bacteria embedded in masses of dead or devitalized tissue was apparently a serious disappointment, which led some surgeons from their experience with severe war wounds to discount the newer antiseptics.

A direct method of investigating action on tissues consists in examining histologically the base and edge of wounds under treatment with the antiseptic, as von Eicken originally did at the early stage. Bennett, Blacklock, and Browning showed that when acriflavine and proflavine are used so as to control sepsis there need be no inhibition of healing. Blacklock, in sections of human material taken during such treatment, found mitoses in various classes of granulation tissue cells and in skin epithelium, as well as active growth of young bone, at depths of 0.018 to 0.2 mm. below the actual free surface. Other properties of antiseptics on tissues may be utilized advantageously—for example, the solvent effect of hypochlorites (eusol) on fibrin and necrotic material.

In the case of fairly resistant tissues, like skin, certain non-irritating antiseptics are available which can be applied in very concentrated form, as for preparation of the skin before operation—for example, mixture of brilliant-green and crystal violet (Bonney and Browning, McLeod and Brown); mercurochrome-220 (Young, White, and Swartz); hexylresorcinol (Leonard and Feirer); and "dettol" (Colebrook and Macted). Some of these are also used in the vagina.

Summary

1. Several types of compounds are now known which, as compared with the old antiseptics, possess a much higher antibacterial power relative to their toxicity for mammalian tissues. A further advantage of certain of these is that serum does not neutralize their antibacterial action.

2. There is conclusive evidence that by their use recent experimental infections with streptococci and other organisms localized in wounds and serous cavities can be cured, whereas saline washings or injections are without effect. Thus a true chemotherapy of local bacterial infections has been realized. Under similar conditions substances such as carbolic acid or mercuric chloride are much less effective, or fail altogether. Curative action on established local suppuration has also been demonstrated under controlled conditions.

3. Antiseptics intended for therapeutic use must not be considered *en bloc* or selected solely on the basis of their ability to kill rapidly some test organism *in vitro*. Each must be examined as regards selective action on various bacteria in protein as well as watery media *in vitro*, and as regards effects on tissues *in vivo*. Such tests give valuable indications, but the chemotherapeutic efficacy of a substance is finally determined by its

influence on the pathogenic action of organisms in an infected host. More extended investigation on these lines is required.

4. The most successful clinical application of antiseptics is likely to be the prevention of infection in tissues liable to contamination, or recently contaminated with bacteria. But limitation of both the extent and duration of established pyogenic infections, and hence of the various consequences, can also be attained. Necrotic or devitalized tissues cannot be sterilized. Accordingly antiseptics must be used as an addition to established physical (operative, etc.) measures and other forms of therapy. Details of procedure cannot be transferred by analogy from one animal species to another, and the surgeon must therefore work out the best methods of utilizing the properties of the new antiseptics in human treatment.

Original investigations referred to here were carried out with the support of the Medical Research Council, which made possible the continued co-operation, on the biological side, of Miss R. Gulbransen, and on the chemical side, at Leeds University, of Professor J. B. Cohen. Facilities for the work were provided at the Bland-Sutton Institute, Middlesex Hospital, and the Pathology Department of the University and Western Infirmary, Glasgow.

According to L. Klein (*Thèse de Paris*, No. 121) some authorities are of the opinion that rice beds have little to do with the spread of malaria. Italian writers, particularly Alessandrini, have even suggested the establishment of rice beds as a prophylactic method against the disease. Although rice beds bring about an extraordinary increase in anopheles, these mosquitos, according to Alessandrini, do not give rise to malaria. On the other hand, the recrudescence of malaria in certain regions where it was very rare before the establishment of rice beds shows that the culture of rice is inadvisable as an antimalarial measure. As, however, rice beds cannot be suppressed without causing serious economic loss to the country, other measures must be taken to prevent the spread of malaria, such as periodical drying of the rice bed for four days every fortnight to destroy the larvae, the introduction of fish for the same purpose, and the prohibition of rice beds in a radius of less than 1,000 metres of a village. Unfortunately, as the natives in the colonies are the slaves of tradition, it is very difficult to make them adopt the smallest modifications as regards the culture of rice, so that the problem of malaria and rice fields is still unsolved.

THE USE OF RADIUM IN CARCINOMA OF THE BLADDER*

BY

A. J. DURDEN SMITH, M.B., B.S.
SURGEON, RADIUM INSTITUTE, LONDON

The views held by urologists and radiologists as to the efficacy of radium in the treatment of bladder tumours vary widely—so widely that an investigator coming new to the subject could not but be impressed by the very marked divergence of opinion even among eminent men who have presumably given radium a fair trial. There are those, for instance, who champion radiation methods so enthusiastically that they use neither excision nor fulguration. Barringer of the Memorial Hospital, New York, is one of these, and all bladder tumours at his clinic have been treated by radiation methods, chiefly radium, for the past eighteen years. There are many others who say that its intervention has been productive of harm rather than good. Among these are many urologists in this country, and radium is used very much less here or on the Continent than in the United States.

In other branches of medicine where there is doubt as to the wisest choice between entirely different methods of treatment it is often found that none of the methods involved is very satisfactory, and it will be admitted, I think, that this is the case in carcinoma of the bladder. This remains true, despite the advances in bladder surgery during recent years, the reason being that surgery still fails in a large number of cases, and that the majority of bladder cancers are beyond the reach of surgery when first seen. It seems reasonable to suggest, therefore, that radium may have something to offer in the treatment of carcinoma of the bladder as it has in other sites, such as the cervix uteri, where surgery, at any rate, has its limitations.

Although radium has been used in the treatment of bladder tumours for years, it is comparatively recently that radium treatment could be discussed and analysed on the same sort of criteria as apply to older and established methods such as surgery. It is true that a comparison of radium treatment with excision is not easy for many reasons, but enough cases have been treated over a sufficient period to enable us to assess its value and to form some idea of what contribution it can make to the solution of a problem which is admittedly a difficult one, and in which advance, even in recent years, has been slow.

Features that Favour Treatment

There are some features of bladder cancers that should favour any form of treatment which has a chance of eradicating the disease. One is that local glandular involvement is late, and, indeed, is often absent even in quite inoperable cases. Another is the rarity of early metastases, although these are present in a high percentage of cases in which the patients die of the disease. Approach to the bladder is easy, and excision in many cases is not a difficult matter. On the other hand, patients with carcinoma of the bladder are past middle life, and are often reduced to poor condition as a result of haematuria or cystitis, or both. The majority of cancers arise on or near the trigone, so that excision is impossible without transplantation of one ureter, or total cystectomy. In addition, there is a large group of cases, varying from 45 to 60 per cent. with different surgeons, which are inoperable when first seen. Faced with such difficulties, radium, if it is an adequate method of attack, is in a

position of advantage, especially with regard to the situation of many growths. It can be used, for example, in cases where the growth is close to the ureteric orifice without grave risk of subsequent stenosis.

Before proceeding further, it must be stressed that, although comparisons are odious here, as in other things, they are in this sort of discussion necessary. A new form of treatment must be judged on its merits, and these can only be assessed in so far as the method of treatment compares favourably or unfavourably with pre-existing methods. And here a difficulty arises at once. It is said, and the view is held by many, that operable cases should be treated by excision, and that radium should only be used for the rest; it is undeniably impossible to compare the methods, because each is dealing with a different type of case. It is important to remember in this connexion that large numbers of malignant bladder growths are inoperable when first seen, by reason of their extent, their fixation, the glandular involvement, or metastases. With regard to operable cases, it is, I think, possible to come to certain definite conclusions as to the use of radium, and these two groups of cases will be discussed later.

Early Radium Methods Reviewed

Early attempts at treatment consisted in the introduction into the bladder, per urethram, of catheters containing radium tubes in the distal end, and this was often combined with external radiation from applicators placed over the suprapubic region. This method resulted sometimes in temporary cessation of haemorrhage and control of symptoms. Later, use was made of ingenious fixing devices, whereby high-content radium tubes could be placed in contact with the growth by vision through a cystoscope. This method had the disadvantages that the time factor could not be prolonged, and that the maintenance in position of such apparatus was a difficult and often painful business.

The suprapubic approach and interstitial radiation were next tried, and glass radon seeds inserted into the growth. As was inevitable, extensive and intractable radium burns rewarded this method, although in a few cases, after much tribulation, the disease cleared up.

The insertion of radium needles gave better results, and this method is still used. The needles are inserted into the base of the tumour, so as to form a field of radiation in the bladder wall deep to it. They have walls usually of 0.5 to 0.8 mm. of platinum, and are of low linear intensity—0.5 to 1. The radiation time extends over a number of days, usually five to seven. The confined space and the irregular bases of many bladder tumours often make it difficult to place needles accurately, so that homogeneous radiation is obtained. In addition, the fact that threads are attached to them makes it easy for them to be displaced, and they have to be removed at the end of the required period of irradiation.

Use of Radon Seeds

Screened radon seeds have none of these disadvantages, and after their introduction by Failla they began to be used extensively by the suprapubic route. In the United States the insertion of screened radon seeds by means of the cystoscope was first carried out by Young and Keyes, and in this country by the late Frank Kidd, and Ogier Ward. At the present time radon seeds are being used more and more in carcinoma of the bladder. They have many advantages, not least among which is the fact that they can be left permanently in position, and so, when inserted by the suprapubic route, the bladder can be closed. They are easier to manipulate than needles, and can be introduced, if necessary, by means of a curved cannula. They are suitable for use in tumours

* Read in opening a discussion in the Section of Radiology and Electrotherapeutics at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

of irregular outline and base, and, on the whole, are more adaptable than needles. For insertion by the cystoscopic route their advantages are obvious.

The filtration and content of seeds vary, but they are commonly either of platinum or of gold, the thickness being from 0.3 to 0.5 mm. The content ranges from 1 to 2.5 mc. each. The length can, of course, be varied at will, but the standard length is 0.6 cm.

The Suprapubic Route

The bladder is opened in the usual way, care being taken to work in a dry field, and to cover the wound edges to avoid implantation. Many surgeons remove a bulky papillary carcinoma with the diathermy before inserting radium; this avoids haemorrhage during manipulation, and reduces the risk of implantation of cancer cells. If needles are used, these are chosen so that their length is suitable for the growth to be treated; it is wise to have at hand needles of several sizes, because the cystoscopic appearances are often unreliable in giving the exact size of the lesion.

In the case of seeds they are inserted into the tumour base, the area of irradiation being well wide of the tumour limits. In papillary carcinoma with little or no infiltration, the seeds are inserted in the bladder wall in one plane. Judgement as to how deep it is safe to place the seeds is difficult in infiltrating carcinoma, and only comes by experience. The bladder is either sutured without drainage—and it is claimed for this method that a considerable number of such cases heal without leakage, thus avoiding wound infection—or a drainage tube is inserted.

The Cystoscopic Method

The other method commonly used is the cystoscopic, and consists in the introduction of screened radon seeds through a ureteric cystoscope, which must be of the flushing type. The cystoscope was first used in this country by the late Frank Kidd, and certain modifications have been made by Ogier Ward. After inserting the instrument, the flexible introducer is passed into the bladder, having previously been loaded with a seed. The sharp end of the introducer is then plunged into the required place in the bladder wall, and the seed expressed by means of a spring handle of the thumb-press type. At the Radium Institute the seeds for this purpose are made with especially sharp points to render insertion easy.

A minute description of the technique would be out of place here; suffice it to say that seeds are introduced as far as possible beneath the tumour, the point of the introducer being inserted through normal bladder just outside the neoplastic area. The procedure is often a tiresome one, and demands great patience. It is sometimes found that the bladder wall is so tough that it is difficult to make the flexible introducer penetrate the requisite distance. On the other hand, when the instrument has to be inserted into tumour tissue, the latter may prove so friable and soft that the seed drops out as soon as it is introduced.

Bleeding is often a great obstacle to accurate implantation of the total number of seeds. Much of this difficulty can be overcome by the use of the flushing instrument, and in the case of Ogier Ward's introducers, they can be used as electrodes to coagulate the tissue either before or after implantation if the growth bleeds too profusely. If troublesome bleeding occurs and a good view cannot be obtained, it is wiser to insert the remaining seeds at a later date.

At the end of the seeding the base of the bladder should be inspected to make sure that no seeds have dropped out of the growth during the operation. If a seed is found lying on the trigone, it is probably because it has been introduced through a portion of growth, the introducer being, not in the bladder wall beyond the growth, but lying free in the bladder behind it. The delivery of the seed into the wall, however, conveys a distinctive impression to the hand, and this should not happen without the knowledge of the operator.

Radiographs should be taken after forty-eight hours and four days, in order to make sure that all the seeds remain in position, and all urine passed by the patient must, of course, be examined to

make sure that seeds are not included. Seeds left lying free in the bladder are passed painlessly at the first urination, as are seeds which drop out subsequently. The patient need not remain in bed more than four to five days, or in hospital more than a week.

Each of these methods, suprapubic and cystoscopic, has advantages. For the suprapubic method it can be claimed that the growth can be inspected more thoroughly and palpated, that biopsy is made easy, and that the introduction of radon seeds is done by direct vision in a good light, and is therefore more accurate. The cystoscopic method has the advantages that the bladder is not opened, that the patient need not be in hospital more than five to seven days, and that in the case of difficulty of introduction or the desirability of splitting the dose, the insertion of the required number of seeds can be done at more than one sitting. The cystoscopic method is not, however, suitable for the treatment of growths in any part of the bladder. Tumours situated in the anterior wall or vault of the bladder cannot be reached satisfactorily, and must be approached by the suprapubic route.

Surgery in Bladder Carcinoma

Before discussing the use of these methods, let us consider for a moment the surgical aspect of the disease. It is generally admitted that operable cases, including those in which transplantation of one ureter is necessary, are in the minority. In a recent series of cases (Macdonald) the inoperable cases amounted to 60 per

Cystoscope of flushing type (Ogier Ward's modification) and seed introducer. The cystoscope has a valvular attachment so that escape of fluid is avoided while inserting the introducer.

cent., and this figure is given by many workers. Total cystectomy is a very severe operation, and although during recent years a few surgeons have improved the technique so that the mortality has been reduced considerably, it is still a procedure limited to very experienced urologists, and is a malignant operation from the patient's point of view. The mortality remains very high, and the subsequent life of the patient is often a miserable one.

The results of surgical procedures—namely, partial cystectomy with transplantation of one ureter if necessary—can only be seen from figures, and these are not easy to interpret and to compare, because of the differing ways in which the authors set them out. The operative mortality has been steadily decreasing, and is now between 10 and 15 per cent.

Macdonald, in a recent series of representative cases, quoted forty-four carcinomata of different types; operative mortality was 13 per cent., and 31 per cent. were alive for three years or more. Although such figures show that treatment by excision leaves much to be desired, the results are such that any other method has to be very carefully considered before it is substituted. These figures apply to 40 per cent., let us say, of the cases. Of the other 60 per cent. it must be admitted that control by diathermy is all that can be offered them, and that cure is out of the question.

Some Results of Radium Treatment

Leaving out for a moment the 40 per cent. operable cases, what has radium to offer the remaining 60 per cent.? At the Radium Institute, London, we have treated 60 cases of carcinoma of the bladder since 1927. The majority of these have been treated by Ogier Ward, and he was responsible for the cystoscopic technique. I quote them here because they were all considered to be inoperable when first seen, either because of the site, extent, or fixation of the growth, or because of the patient's general condition.

Except in those cases in which the growth had recurred after excision, and in those few which were treated by the suprapubic route, no histological data were available, and diagnosis was made on the cystoscopic findings. This is, of course, an important point, and must be taken into consideration when the results are assessed. It may be that a small percentage of these growths were not malignant, and since papilloma of the bladder is sensitive to radium this factor may be reflected in the results.

Many of the cases are too recent to be of value in this discussion, but thirty-eight of them were treated up to 1931, and I shall only consider these. They are divided into two groups: the papillary and the infiltrating types. Twenty-three were of the papillary type; of these, twenty were treated by the cystoscopic method with seeds, needling by the suprapubic route being the method in the other three cases. Four cases were recurrent after partial cystectomy, and two of these were controlled for periods of two and a half and three years respectively. Of the total number (twenty-three), ten have remained well, five for five years, two for four years, and three for three years after treatment. Of the fifteen infiltrating carcinomata, ten were treated by the cystoscopic method and five by the suprapubic route. Of these, three are alive and well, one for five years, one for four years, and one for three years after treatment. (Three cases in each group were untraced.) These figures are meagre, but they give some idea of the results that have been obtained in a group of cases, all of which were in a very advanced condition when first seen. Of the cases of papillary carcinoma, 43 per cent. were free from disease for three years and more, while 20 per cent. of the infiltrating cases were alive and well after the same period.

Table Showing Results in Thirty-eight Cases of Carcinoma of the Bladder

Type	Number Treated	Cystoscopic Method	Suprapubic Route	Alive over—		
				3 yrs.	4 yrs.	5 yrs.
Papillary...	23	20	3	3	2	5
Infiltrating ...	15	10	5	1	1	1
Total ...	38	30	8	4	3	6

In the United States, where radium has been used for bladder carcinoma longer than in this country, Keyes, Neill, Young, and Barringer, among others, began to report results as early as 1928. Neill (Baltimore) reported on a series of cases, 168 of all types, treated by radium. Inoperable cases numbered 111, and of these 8.9 per cent. were free from disease for three years or more. The remaining 57 were operable, and of these 35.5 per cent. survived the three-year period without disease. At the Memorial Hospital, New York, all bladder cancers, whether operable or inoperable, have been treated with radium for eighteen years, excision never being used. In 109 cases Barringer reports 43 per cent. three-year cures in papillary carcinoma, and 27 per cent. in infiltrating carcinoma.

Burman, in 1931, quoted results in 111 cases. In the papillary type 17 per cent. of cures were obtained (of these cases the percentage cure in operable cases was more than twice that in inoperable ones). In the infiltrating type 16 per cent. were cured, and here again the percentage in the operable cases was very much higher. Pfahler, in 1931, reported 19.3 per cent. five-year cures in forty-three inoperable cases of all types by coagulation and radium. Dargatzis, in 1933, reported results in twenty-two cases treated by the insertion of needles by the suprapubic route. Of these, seven were of infiltrating carcinomata, three of which were free from disease eight years, seven years, and four years respectively. The method of treatment is interesting, in that a rubber balloon filled with fluid is placed in the bladder in order to keep the bladder wall away from the radium in the growth. It is claimed that subsequent discomfort is minimized by this procedure, and that post-radiation cystitis is much less. The mortality is low—Barringer claims that in his cases it is 7.2 per cent.—and complications are rare.

The aftermath of treatment may be unpleasant, especially where large doses have been given over a wide area. Radium causes a slough to form, which may take months to separate—very much longer than after fulguration. Phosphatic deposits may be found on the area treated, and slough and deposit sometimes make it difficult to be sure whether there is still growth present or not. From the patient's point of view the prospect is often not a pleasing one, but to say that every patient treated by radium is made miserable for months after his treatment is simply not true. In fact, the after-symptoms vary in severity, from dysuria and frequency of a serious kind to transient discomfort which worries the patient very little. There are many patients who are made worse by radium treatment, chiefly those suffering from infiltrating carcinoma of great extent, where the dosage over a wide field is liable to act on the whole bladder, causing a very severe cystitis; if these patients have received a dose which is insufficient they are made miserable without the disease being eradicated. Experience will, we hope, lead us to avoid these cases.

The results of radium treatment show that papillary carcinoma is sensitive to radium, and that it is amenable to treatment by radium when it is not too extensive, and

when the growth is confined to the bladder. The infiltrating type, on the other hand, is more radio-resistant, and operable cases of this type should, I think, be treated by resection. Inoperable cases must be carefully considered. If they are extensive within the bladder their extravascular spread probably renders them incurable by any means, and widespread interstitial irradiation runs the danger of making the patient more miserable than he was before. Experience with these sixty cases at the Radium Institute seems to show that cystoscopic implantation of seeds should be limited to those cases of papillary carcinoma where the growth or growths are not more than 2 to 3 cm. in diameter, and that larger growths should be dealt with by the suprapubic route; that operable infiltrating carcinoma should be resected; and that great care must be taken in selecting inoperable cases suitable for radium treatment.

ALLERGIC FACTORS IN RHINORRHOEA AND NASAL CATARRH*

BY

THEODORE JUST, M.B., B.CH., F.R.C.S.

AURAL SURGEON IN CHARGE OF OUT-PATIENTS, ST. BARTHOLOMEW'S HOSPITAL

The term "allergic disease" has been introduced into medical literature by American investigators (Cooke and others), to designate a number of conditions which show one common aetiological characteristic—namely, hypersensitiveness to proteins or other substances that are innocuous to normal people. For the most part the patients suffer from acute attacks, while in the interval between two attacks they are in good health. Often, however, especially in the more severe cases, they present symptoms of their illness continuously, and suffer from acute exacerbations.¹

I do not propose to deal with bronchial asthma, skin conditions, or true hay fever, since these are already clinical entities, but I shall restrict myself to allergy as seen by the rhinologist in a rather indefinite form, either complicated or uncomplicated, by catarrh of bacterial origin. The following headings may be mentioned: hypersensitiveness to (1) drugs; (2) various pollens; (3) so-called animal proteins; (4) foodstuffs; (5) bacterial products; (6) colloidal substances of unknown composition, the presence of which in the air is due to climatic influences (miasma).²

It is a well-known fact that certain people are hypersensitive to certain drugs, but in one important respect they differ from allergics: the symptoms they exhibit with a small dose of the particular drug are the same symptoms exhibited by normal people with an excessive dose. The true allergic exhibits symptoms which are totally different from any that might occur in persons non-sensitive even on really excessive dosage. I propose to pass over hypersensitiveness to various pollens, to animal proteins, and to foodstuffs, but would like you particularly to bear in mind hypersensitiveness to bacterial products.

It has been thought that there was an anaphylactic element in allergic diseases, but the main arguments against this theory are: (1) Allergic disease is often inherited; anaphylaxis is not. (2) Allergic symptoms are sometimes shown the first time the person comes in contact with the incriminated substance. (3) Allergy cannot be transmitted passively to animals; in anaphylaxis this experiment usually succeeds. (4) The symptoms

of allergy differ largely from those of anaphylaxis, but show resemblance to those of drug idiosyncrasy.

You are all familiar with the typical case of vasomotor rhinitis or paroxysmal rhinorrhoea associated with violent sneezing attacks, and a pouring of clear watery fluid from the nose to such an extent that patients are compelled to use towels instead of handkerchiefs for relief. But I believe, though in many cases I have no definite proof of the statement, that in a large number of so-called chronic catarrhs there is a very definite allergic factor; and I am sure that it is concerning the latter type of case that we should attempt to increase our knowledge.

Factors Operating in Vasomotor Rhinitis

The factors generally found in cases of vasomotor rhinitis are: (1) some personal idiosyncrasy; (2) a sensitive condition of the nasal mucous membrane; (3) some outside irritation; and (4) a supposed nervous element. Of these I consider the first all-important, and the last almost negligible.

As regards personal idiosyncrasy, we know that allergics, whether they be hay fever patients, asthmatics, or persons sensitive to animal emanations, on cutaneous testing, do not only react to their own usually specific protein, but also to numerous others, and that their sensitivity to these various proteins may vary from day to day. According to van Leeuwen, all allergics are sensitive to human dandruff, though varying in their reaction to other proteins. With this fact I will deal in greater detail later.

Our reasons for suspecting increased sensitivity of the nasal mucosa are rather empirical. The nasal mucosa either appears normal, pale, velvety, and slightly congested, or there may be whitish patches on it. This condition may apparently be rendered less liable to irritation by either cauterization or ionization. In certain patients this treatment affords either relief or cure, but it should be borne in mind that the sensitivity is often only to some specific irritant in the allergic person.

It is fully granted that the external irritation, acting on the mucous membrane of the allergic, is the trigger which sets off the attack. The nervous element is, in my opinion, the one most open to doubt. With most patients I consider that the discomfort, nuisance, and distress of repeated attacks of severe rhinorrhoea, which come on at least expected and most inopportune moments, are the cause of the patient's neurosis rather than the result.

Some Causes of Simple Vasomotor Rhinitis

Let us now consider simple uncomplicated vasomotor rhinitis, which is a condition with which we are all familiar. I am not going to deal with its pathology or clinical manifestations, but I would like to suggest one or two causes of the condition. St. Clair Thomson, in the 1916 edition of his book *Diseases of the Nose and Throat*, stated that vasomotor rhinitis was more common in the young male than in the young female. I am sure you will all agree with me that in these days the disease is much more common in the young woman. I think the reason is, not that there are more allergics, or that the young women are more neurotic, but that practically all women do use face-powder. We are all familiar with the white sheen that is seen on the septum and turbinates of the more heavily made-up woman. Many women are particularly susceptible to orris root, and I am told on good authority that orris root is to be found in certain makes of powder. In fact, one patient of mine told me that she could not use a powder in which orris root was known to be present, as it "was death to her." Quite often the changing of the make of powder is a valuable aid to treatment; it is more than the physician can do to stop its use.

* Read in opening a discussion in the Section of Oto-rhino-laryngology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Sensitivity to Staphylococcal Infection

I mentioned at the beginning of this paper that patients could be sensitive to a specific bacterial protein. Many patients suffering from typical vasomotor rhinitis have cracks in the skin about the anterior nares, and these cracks have been looked upon as a necessary adjunct to the disease. We all know that unless these cracks are cleared up there is little hope of alleviating the vasomotor rhinitis, whatever treatment to the nasal mucous membrane may be employed. But we see, in our specialty, many cases of vasomotor rhinitis without any obvious cracks; and we have numerous cases of vestibulitis, a condition that is most certainly of staphylococcal origin, which, after persisting for weeks, months, or even years, have no vasomotor symptoms. (The infection of the cracks is always staphylococcal.)

I would suggest, therefore, that the cracks occasionally seen in the nares of patients suffering from vasomotor rhinitis are not necessarily due to the allergic condition of the nose, but that the patient may have had a very mild and unnoticeable staphylococcal infection of the anterior nares, and, being sensitive to the specific staphylococcus protein, the subsequent vasomotor symptoms were caused by the patient's allergy to that particular protein. At any rate we do know, however far-fetched the idea may seem, that vasomotor rhinitis associated with cracks will not clear up until the latter are cured. I have no definite proof that sensitivity to staphylococcal protein is the cause of many cases of vasomotor rhinitis.

In some cases of rhinitis, or, as the patient expresses it, chronic catarrh, there is evidence that the condition may be due to the patient's sensitivity to the protein of a specific organism. It must be in everybody's experience that in many patients complaining of chronic catarrh there is apparently no abnormality in the nose, sinuses, or nasopharynx. On careful questioning these patients give histories of mild stuffiness of the nose with a slight or negligible watery discharge, while at other times they have symptoms of the typical bacterial cold, with a thick muco-purulent discharge. I believe that these patients are really allergics who are sensitive to the specific proteins of one or other of the bacteria which may cause rhinitis, and that the acute exacerbations of the catarrh are due to the bacterial infection, and the intermittent slight catarrh to the allergic reactions of the patient to the specific bacterial protein.

Again, it is a common fact that in many cases of vasomotor rhinitis, especially of the unilateral type, on careful examination, a latent and unsuspected antral infection is found on the homolateral side, and that on clearing up the infection the vasomotor symptoms subside. In these cases I believe that the running from the nose is a local condition, caused by intermittent leakage of the specific protein from the infected antrum.

Nasal polypi are often found in conjunction with asthma, much less commonly with simple vasomotor rhinitis, and it is known that in asthmatics who have this condition local removal of even small polypi causes a diminution of the symptoms. The polypi have been regarded by certain physicians as part of the allergic swelling of the nasal mucosa, but I believe that, however small, they are evidence of a local ethmoiditis, and that their removal allows the secretion in the cells to be either washed out or blown clear, thus reducing the chance of affection of the sensitive mucous membrane of the nose by that specific bacterial protein.

A patient of mine suffered from very severe asthma, which completely incapacitated her. When I first saw her she had a mild ethmoiditis, which I treated by an anterior middle turbinectomy and curetting of the ethmoid cells. This treatment was followed by a series of minute doses of an autogenous vaccine, with improvement. Small polypi then began

forming with recurrence of the asthma, which was temporarily relieved by removal of the small polypi and with continuance of the vaccine therapy. However, in spite of several local removals of the polypi, spread over many months, her asthmatic condition became very much worse. She had, I should have mentioned, an intercurrent antral infection which increased the symptoms, but on opening and washing out the antrum the symptoms improved, and she was back at her old level. This antral infection was purely an intercurrent event in my opinion, but, as I have said, the continuance of the ethmoiditis caused her to be completely incapacitated by her asthma. I therefore decided to perform an external ethmoidectomy, with a view to exenterating all the ethmoid cells. Since then her asthmatic condition has been wonderfully improved. She still has her ups and downs, and has pocketed pus behind the scar or in the nose on occasion, when her symptoms are always more pronounced but are almost immediately alleviated by drainage of the cooped-up secretion. That she has these recrudescences is probably due to faulty technique of my own. She has continued with intermittent courses of autogenous vaccine in minute doses; any large increase in the dose immediately brings on an exacerbation of the asthmatic symptoms and nasal discharge.

I must apologize for quoting a case of asthma as illustrative of some of my points, but it was one of the most severe cases I have had to deal with, and the results, though not dramatic, were satisfactory, and, I think, have a bearing on my point concerning specific bacterial protein sensitivity.

Autogenous Vaccines in the Allergic

Out of the case I have just quoted there emerges another question, that of giving minute doses of vaccine to asthma patients with apparent improvement, whereas the ordinary minimum dose of vaccine given to patients suffering from any form of bacterial rhinitis causes an exacerbation of the symptoms in the allergic. It is known that one can immunize people sensitive to a specific protein by injecting infinitesimal doses of that protein at frequent intervals, say every other day or twice a week, whereas larger doses of the same protein cause increased sensitivity. Ipecacuanha is a case in point.

We know that certain bacteriologists in cases of chronic catarrh are accustomed to give infinitesimal doses of autogenous vaccines over a long period of time, with improvement, the doses being minute in comparison with the ordinary doses of vaccine given, either for treatment or for prophylaxis, in bacterial catarrhs. I would suggest that the results are obtained, not by an immunization of the patient against these organisms, but by the desensitization of an allergic patient to specific protein of the bacteria in his nose. Further, we have all seen patients who complain bitterly of catarrh when in theatres, cinemas, and close warm rooms where people are assembled, whereas they are completely free from it when out of doors, whether in hot, still weather or whether walking over wind-swept moors. One would naturally conclude, I think, that people suffering from a bacterial catarrh would be worse under the conditions of cold and wind. Even the normal person experiences running from, and stuffiness of, the nose under these conditions.

As I have mentioned, van Leeuwen states that all allergics are sensitive to human dandruff. He is also the pioneer of the "miasma theory" of allergic irritation. This theory presumes that allergic patients may be sensitive to foreign proteins in the air, which are in such infinitesimal quantities that their presence cannot be proved. It is not hard to visualize the fact that human dandruff may be present in sufficient quantity in the air of crowded rooms and theatres to satisfy these postulates in the case of allergic people. This may be an explanation of this type of catarrh, for in most cases when the patients arrive in the cool quiet of the consulting room their upper air passages appear normal.

I apologize for being so unscientific and for having stated so many unproven opinions, but I believe that the study of allergy in connexion with our specialty is still in its infancy, and that several aural conditions, which are now tentatively supposed in some cases to be partly allergic, will in the future be definitely established as such. Out of my ignorance of the subject I fear I have been provocative to those who know more. My only hope is that I may have stimulated the more knowledgeable to a good discussion from which some of us may learn something for the future.

THE ADVANTAGES OF INTRAVENOUS (EVIPAN) ANAESTHESIA IN OPHTHALMIC SURGERY

BY

T. KEITH LYLE, M.B., M.Ch.CANTAB.,
 M.R.C.P.LOND., F.R.C.S.ENG.

SENIOR RESIDENT MEDICAL OFFICER, ROYAL WESTMINSTER OPHTHALMIC HOSPITAL

AND

F. G. FENTON, M.B., B.S.MED.

JUNIOR RESIDENT MEDICAL OFFICER, ROYAL WESTMINSTER OPHTHALMIC HOSPITAL

Although intravenous anaesthesia with evipan is used on quite a large scale in many hospitals to-day for various types of cases it is perhaps not fully realized that it is of particular value in ophthalmic surgery. This article is designed not to introduce the authors as authorities on evipan anaesthesia, but to set down their experiences with a small series of some eighty-six cases at the Royal Westminster Ophthalmic Hospital and their conclusions therefrom, as we feel certain that our findings may be of interest and of practical value to many persons engaged in ophthalmic practice who may not have used this type of anaesthesia in their operative work.

As only a minority of ophthalmic operations are performed under general anaesthesia our series is necessarily small, but so superior have been our results with evipan in comparison with other forms of general anaesthesia in our operative work at this hospital, both from the ease and speed of induction, the saving of time, the simplicity of apparatus, the optimum conditions for the surgeon, patient, and anaesthetist, and the apparent great margin of safety, that we have adopted evipan as the routine anaesthetic for practically all cases requiring general anaesthesia. In every case in our series evipan gave more or less complete satisfaction to the surgeon, and we have not had any worry, from the anaesthetist's point of view, in any patient. Our observations will be presented under the following headings: technique of injection, dosage, etc.; general advantages of evipan; special advantages in ophthalmic surgery; and an analysis of our series.

Technique of Injection, Dosage, etc.

With a little experience the optimum dosage can be very accurately calculated after a rapid consideration of the length of anaesthesia required, of the patient's approximate body weight and age, and whether of a robust, frail, or toxic constitution. Our dosage varied from 4.5 c.cm.* in the case of old toxic patients to a full 10 c.cm. in strong, healthy adults. In a few of the latter we found it necessary to give as much as 12 c.cm. to

* Strength of solution is 1 gram of sodium evipan per 10 c.cm. of distilled water.

produce the requisite degree of relaxation. Healthy children required a relatively much larger dose than adults, a healthy average child of 4 years taking 5 c.cm., while children of 10 years and upwards generally required a full 10 c.cm. Old, feeble persons required very little more than 4 c.cm.

Having roughly estimated the required dosage for the individual case, a 10 c.cm. syringe is fully charged with a previously mixed solution of evipan, and the needle introduced into a vein in the arm, the patient being instructed to count slowly aloud. When consciousness is lost, as indicated by the cessation of counting, the amount already injected is noted and the injection continued until as much again has been given, in accordance with the practice of the German school. The needle is kept in the vein, and the surgeon then grasps the conjunctiva with forceps. If the dosage is insufficient, as indicated by movements of the patient's limbs, a small additional injection is made until the patient relaxes, the anaesthetist being careful not to exceed his original estimated dose by more than 1 to 2 c.cm. unless the movements of the patient indicate a further dosage. After consciousness is lost the jaw is kept supported to keep a clear airway. *No preliminary medication is required or should be given.*

Carbon dioxide and oxygen for inhalation is kept at hand in case of respiratory failure, but we have not found the use of this emergency treatment necessary in any of our cases. In many of the older cases a severe sneezing reflex, several times repeated, occurs during early manipulations of the conjunctiva. This does not, however, seriously interfere with the course of the operation. A delay of one or two minutes before commencing the operation frequently eliminates this phenomenon. It has not occurred in any of the children in the series. With children, the arm must be kept rigid during the injection, as otherwise the needle may be dislodged by a sudden movement as the patient loses consciousness.

In the average case under the above technique the duration of anaesthesia suitable for ophthalmic surgery is from fifteen to twenty-five minutes. In very short operations a reduced dosage is given, and when more prolonged anaesthesia is required a further injection may be given when the effects of the original dose show signs of wearing off. This appears to act very satisfactorily. Our longest case was on the operating table for one hour and fifteen minutes, during which time a total of 14.5 c.cm. was given in two separate injections, the anaesthesia being satisfactory throughout.

General Advantages of Evipan

Evipan may be given with safety to patients of any age, provided a very small palpable vein can be found. We had no difficulty in this respect even in very young children. The youngest patient in our series was 4 years of age and the oldest 85.

The contraindications are very few—mainly severe disease of the liver and of the kidneys—and it appears to be safe to use the method even in severe diseases of the cardiovascular and respiratory systems, where inhalation anaesthesia may involve grave risks. The induction is very rapid. The material is inexpensive, requires an absolute minimum of apparatus, and does not need any special skill on the part of the anaesthetist. The period of recovery is very rapid, several of our cases being able to talk rationally within fifteen minutes of leaving the operating table. In the majority of our cases there were practically no after-effects attributable to the anaesthetic. The adult patients were in all cases very pleased with the anaesthesia.

In this connexion it is interesting to note that one of the authors had an evipan injection for the removal of some teeth, having previously at one time or another taken most

inhalation anaesthetics. He considers evipan far superior to anything he has previously experienced.

In the stress of circumstances it is possible for a surgeon to give the anaesthetic and carry on the operation with a minimum of nursing assistance and practically no danger to the patient. Evipan may be given without danger with a partially full stomach. Owing to the great rapidity of induction, the total time required for an operation is very materially reduced, especially with several consecutive short operations.

Special Advantages in Ophthalmic Surgery

The whole of the face and head is left free for the surgeon, which is a considerable help in eye operations. As most ophthalmic operations are of short duration, a single evipan injection is peculiarly suitable to most such. We have found it very suitable for cases of squint in children, for excisions and eviscerations of the eyeball, for acute glaucoma, plastic operations—in short, for practically all eye operations where a general anaesthetic is advisable.

Under evipan anaesthesia the intraocular tension falls, both in eyes with normal tension and in those with raised tension. This was demonstrated in selected cases in our series by palpation and by the use of the Schiötz tonometer. This is a very advantageous factor in operations for acute glaucomatous conditions. In a considerable number of ophthalmic operations the subjects are old, enfeebled persons, perhaps suffering from diabetes, tuberculosis, or other constitutional diseases, in whom inhalation anaesthesia frequently involves grave risks. In the majority of these cases evipan may be given with safety, with every satisfaction to the patient and surgeon alike.

Analysis of Our Series, with Comments

1. *Excision of Eyeball.*—Evipan is ideal for this operation, and we have now adopted it as the routine method of anaesthesia. Thirty-nine operations were done, the age of the patients varying from 30 to 85 years. Particular mention should be made of the advantages over inhalation or local anaesthesia in the following cases:

(a) I. B., male, aged 58 years, an advanced case of Graves's disease with chronic iridocyclitis from corneal ulceration, due to severe proptosis.

(b) A. S., male, aged 66 years, severe arteriosclerotic and hyperpictic, with recent hemiplegia and mental changes.

(c) W. J., male, aged 72 years, very feeble patient with myocardial degeneration and chronic bronchitis.

In all these cases anaesthesia was most satisfactory, and there were no untoward after-effects. Another patient, M. P., male, aged 65 years, was feeble and cachectic, and clinically his liver contained large masses of secondary growth. He was given evipan for removal of a secondary glaucomatous and painful eye, the seat of a primary malignant melanotic tumour. No ill effect followed, although it is said that severe liver disease is a contraindication to the use of evipan.

2. *Evisceration of Eyeball.*—Nine cases, age of patients varying from 9 to 75 years.

3. *Operations for Glaucoma.*—Six cases, consisting of four trephines, one Lagrange's operation, and one posterior sclerotomy. The only difficulty here, as in any general anaesthetic, is the tendency of the eyeball to roll upwards, although this tendency is much less noticeable with evipan than with inhalation anaesthesia. We have found that the intraocular tension is always lowered; this is easily demonstrable by palpation, and we have shown it conclusively by the Schiötz tonometer to be reduced by as much as 10 mm. in some cases.

4. *Lid Operations and Plastic Operations on Sockets.*—Eight cases. The great advantage here is that distortion of the eyelids with local injection fluid is avoided. One case, J. W., male, aged 66 years, underwent a successful operation for paralytic ectropion (due to facial palsy complicating middle-ear disease), fascia lata strips being taken from the thigh and used as slings. The operation lasted one and a quarter hours, and anaesthesia was satisfactory throughout, the total

amount injected being 14.5 c.cm. (given in two successive injections). Another case worthy of mention was H. S., male, aged 43 years, suffering from fibroid phthisis, who underwent a "plastic operation on socket" with good result.

5. *Squint.*—Twenty cases, consisting of eighteen "tenotomies and advancements" and two tenotomies. In one case, a nervous female aged 18 years, operation was commenced under local anaesthesia, but the patient was unable to keep still, and so an injection of evipan was given immediately, and the operation proceeded with satisfactorily. Inhalation anaesthesia would have been impossible owing to the fact that the patient had recently had a meal. Evipan has not been used very considerably for squint, because for obvious reasons local anaesthesia is to be preferred when the patient is sufficiently old to exercise self-control.

6. *Attempt to Remove Deep Intraocular Foreign Body.*—One case; satisfactory anaesthesia.

7. *Opening of Lachrymal Abscess.*—Three cases.

Summary

1. The advantages of intravenous anaesthesia with evipan in ophthalmic surgery are shown.

2. A series of eighty-six cases is presented, showing very satisfactory results with no complications.

We are indebted to the members of the honorary staff of the Royal Westminster Ophthalmic Hospital for their kind co-operation in the use of evipan for their cases.

CHORIONIC CARCINOMA

WITH A REPORT OF A CASE FOLLOWING RUPTURED TUBAL GESTATION

BY

RUFUS C. THOMAS, F.R.C.S.ED., M.C.O.G.

Cases of chorionic carcinoma are always of sufficient interest and rarity to merit publication. According to DeLee's "hydatidiform mole preceded the development of this disease in 33 to 40 per cent. of reported cases." Again, Eden and Lockyer state that "in two out of every three cases the immediately preceding pregnancy terminated in abortion." Both the above statements presumably refer to uterine pregnancies. The urgent symptom would therefore be uterine haemorrhage, and the fact that it was preceded by an abortion, either of the ordinary type or more especially of a hydatid mole, would tend to put one on guard. Chorion, wherever situated, may, however, be liable to malignant degeneration. DeLee states that "ectopic gestation may undergo this [hydatidiform] degeneration." Tubal and ovarian pregnancies must therefore share in the general danger.

Chorionic Carcinoma of Tube or Ovary

The clinical picture of a malignant degeneration of a chorion situated in the ovary or tube is nevertheless very different from that of the uterine variety. Such cases must be very rare indeed, and, occurring as they do without the usual symptoms of the uterine type, coupled with the fact that the growth is hidden away in the abdominal cavity, must give rise to much confusion in diagnosis. There is not always uterine bleeding to warn the patient that something is wrong. Advice would tend to be sought late, thus giving further time for the condition to develop. Pain in the abdomen or the presence of a tumour in the lower abdomen following an operation for ectopic pregnancy would be the probable reason for seeking advice.

The literature yields the following information. Risel collected eleven cases of primary chorio-epithelioma of the tube, and reports a case of chorio-epithelioma developing in the pelvis, proved at subsequent operation two

and a half months after removal of tubal gestation (about six and a half months after this had started). The woman died shortly after the second operation, and a post-mortem examination showed no growth in uterus or genitalia, but metastases in liver and lungs. Liepmann¹ reported seven more. In one case recorded by Davidsohn² chorio-epithelioma formed in the stump of a tube excised for ruptured tubal gestation. Lefquist³ gives an account of a tubal pregnancy removed from a tube which was left *in situ*. Two years later a pregnancy recurred in the same tube, which was removed. Pathological examination revealed an early primary chorio-epithelioma of the tube. Hartz⁴ described a case of ruptured tubal gestation in which there were extension of chorionic epithelium into the wall of the tube and chorionic epithelial cells in the lumina of some of the veins. The patient was well two years afterwards. In his paper Hartz states that "primary chorio-epithelioma of the Fallopian tube is of comparatively frequent occurrence when we take into consideration that tubal gestation forms but a small proportion of all uterine pregnancies. Of 300 chorio-epitheliomas up to 1905 the primary tubal variety comprised 3.5 per cent." He also states that "metastatic growths occur from tubal growths just as readily as they do from the uterine variety."

Vaginal Metastasis

Duggan,⁵ in the report of his case, says that the patient came for treatment of "a rather friable, purplish swelling on the right vaginal wall. A mass was felt in the left vault, not movable, irregular, and slightly tender. Uterus slightly enlarged." Removal of both ovaries and tubes and supravaginal hysterectomy were carried out. The left tube was ruptured. Pathological examination showed chorionic carcinoma. X-ray and radium treatment were given, and when the patient was seen two years later "pelvic examination revealed no sign of recurrence—she had gained weight and strength." Bethel Solomons and Smith⁶ recorded a case almost identical with Duggan's, and both are very interesting in that a vaginal metastasis was present at the time advice was first sought. Solomons and Smith seem to have been in doubt as to whether their case was secondary to tubal gestation, as "the chance of it being secondary to tubal pregnancy is most doubtful, for her periods had always been absolutely regular." But the history they give surely does not agree with this, for they state "she was sent to hospital because of continuous hæmorrhage since her last menstruation, which had started three weeks before admission." Obviously her last period was most irregular. And, equally obvious, before admission she could have had a tubal pregnancy of nearly six weeks' duration which ruptured three weeks before the patient was seen by them. Chorionic carcinoma may have developed at any time within these limits. It is even possible that the previous (?) normal menstrual period was really uterine bleeding associated with a small unnoticed attack of pain due to commencing rupture of the tube.

Miles Phillips⁷ had a case of ruptured left tube, with "a small nodule of adherent blood clot on the bladder wall." Tube and nodule were excised. After chorionic carcinoma had been demonstrated microscopically the uterus was curetted, nothing abnormal being found. Six weeks later there was recurrence in the left broad ligament, "an ovoid purplish nodule in the anterior vaginal wall," and a nodule on the bladder wall at the site of the previous nodule. There was also a mass at the root of the mesentery of the small intestine. Total hysterectomy with removal of broad ligament growth, all appendages,

and the bladder nodule was then done. The mesenteric growth was irremovable. All these showed chorionic carcinoma. Three years later she was alive with no signs of recurrence in the abdomen or elsewhere. Fleurent,¹¹ in his case report, quotes Risel's twelve cases, and says that accounts of twenty others were given between 1905 and 1930. If we add his case, Duggan's, Stein's, and mine, the number up to date would appear to be at least thirty-six.

Pathology

It is interesting to recall that Marchand divided the disease into two groups—atypical or benign, and typical or malignant. The benign is characterized by comparative or complete absence of Langhans's cells, and to this type Ewing gives the name "syncytioma." Lynch and Maxwell¹² state "the prognosis in syncytioma is essentially favourable, since the process advances slowly, and the life of the wandering cells is short." Referring to the malignant type, they say "the tumour seems to have a more rapid course, and to metastasize more quickly than does chorio-epithelioma of the uterus. Albert's case and that of Hartz are the only ones which recovered." Duggan's and Phillips's cases are apparently two more.

The degree of malignancy seems to depend on the presence of proliferating and atypical cells of Langhans's layer, which are always present in the malignant type, even in the metastases. Secondaries may be found in the abdomen, spleen, lungs (very common), liver, vertebral column, vagina, and brain. Ovarian changes associated with the disease are well known. Lynch and Maxwell¹² say "there is no doubt but that pronounced cystic changes in both ovaries occur so frequently with chorio-epithelioma as to constitute a specific anatomical feature of the disease." In this connexion, Friedlander¹³ quotes Zondek and Aschheim, and Evans and Smith, as showing this formation of lutein material to take place after implantation of anterior pituitary and ovarian substance in animals, and Murati and Adachi as having produced the same results with the placenta. Urine from a case of chorionic carcinoma may contain as much as 500,000 mice units of anterior pituitary hormone per litre, compared with 8,000 to 12,000 units in normal pregnant urine. Does this excess of hormone hold the secret of both chorionic carcinoma and lutein cyst formation?

Friedlander also quotes Oskar Fraenkl as showing that the serum of a normal pregnant woman is able to destroy foetal tissue from placenta, liver, or kidney, while the serum of a woman suffering from chorio-epithelioma does not possess this lytic action. He concluded that the formation of chorio-epithelioma is due to the absence from the blood of the pregnant woman of the syncytiolytic properties of the serum, and believes that spontaneous cures are due to a recovery of these properties. We do not know what limits the normal invasive power of the chorionic epithelium. That there must be some limiting agent is obvious. If Fraenkl's theory holds the explanation, it could be proved by the injection of serum from a normal healthy pregnant woman into a series of cases of chorionic carcinoma. Such a serum would be very easily secured. Theoretically, it should be obtained from women three to four months pregnant, when limitation of the invasive power of the chorionic epithelium should be taking place and the syncytiolytic properties of the serum presumably be at their height. As a control, estimation of the urine as regards the number of mice units (Aschheim-Zondek) of anterior pituitary hormone might be made, and only that serum the urine of whose donor contained less than 12,000 units be used for the purposes of treatment.

History of Case

The following is the history of my case of ruptured tubal pregnancy which was followed by chorionic carcinoma.

The patient, a Hindu, was admitted into the Irwin Hospital, Jamnagar, suffering from pain in the abdomen, with slight, dark-coloured haemorrhage from the uterus. She had missed two periods. Examination revealed a small tender mass in the region of the right tube, and a diagnosis of ruptured ectopic gestation was made. I operated upon her the same day, and found a tubal gestation which had ruptured intraperitoneally. There was not a great quantity of free blood, and not many clots. The tube was removed, the clots were cleared out, and the abdomen was sponged dry and then closed. Her immediate convalescence was uneventful, and she left the hospital three weeks later.

Two months afterwards she was again admitted. She was now looking very ill, and complained of a swelling in the right side, with considerable pain in the lower abdomen. There was no haemorrhage or discharge from the uterus. Palpation confirmed the presence of the tumour in the right pelvic region, and vaginal examination showed that the tumour was in very close proximity to the uterus, which was enlarged to the size of a three-months pregnancy. The upper surface of the tumour reached well above the brim of the pelvis. The woman had lost weight appreciably, and was looking anaemic and obviously worried. I opened the abdomen again, and found the whole of the right side of the uterus and the right broad ligament covered with a soft, friable, dark-grey-coloured growth. Its nature was only too obvious. It had already begun to spread towards the bladder, and there were several small masses on the peritoneum of Douglas's pouch. The right cornu of the uterus was the seat of a somewhat larger mass, and a small piece was taken from this situation for microscopical examination. There was no possibility of benefit from excision of the uterus, as this would have only taken away about a quarter of the growth. The bladder and Douglas's pouch were already involved. The site of the ectopic was a mass of growth. The abdomen was closed on the tragic sequel to what had been a successful operation for ruptured ectopic gestation. The small piece which had been removed was sent to the Haffkine Institute, Bombay, and a report was received ten days later, confirming that the growth was chorionic carcinoma. The slide which the director of the institute sent me was typical of chorionic carcinoma of the uterus.

At this time it struck me that a few doses of deep x rays might do the patient some good. They could, at any rate, do no harm, and there was no other possible method of treatment. She was therefore sent to the x-ray department, where she received two "massive" doses at intervals of three weeks. I left India about a fortnight after the second dose, so am unfortunately not able to give any later information than up to this date. At this time, however, the tumour had definitely begun to retrogress, and was about half the size it was on admission. The patient's general condition was also much better, and her pain was decidedly less. Locally, therefore, deep x-ray therapy had certainly had some beneficial effect. There was always the possibility of metastasis having already taken place, but clinically there had been no signs of this. I do not know whether deep x-ray therapy was continued after I left Jamnagar. In view of the benefit already experienced it is to be hoped it was.

Summary and Discussion

Though the story must remain unfinished the following conclusions can be drawn:

1. Ruptured tubal pregnancy, removed by operation, was followed within a very short time by malignant disease of the chorion.

2. Three months after operation the growth had become palpable above the pelvic brim, and was found at the second operation to have involved the whole of the right broad ligament, the right pole of the uterus, the bladder, and Douglas's pouch.

3. The symptoms were: lower abdominal pain, cachexia, and a tumour in the right iliac fossa. There was no uterine bleeding or discharge.

4. Two "massive" doses of deep x-ray therapy resulted in definite retrogression of the tumour, considerable lessening of pain, and improvement in the general condition of the patient.

To my mind there are three possible ways in which this case can be explained. In considering them we must remember that we are dealing with a gestation sac which had ruptured into the peritoneal cavity. The possibilities are as follows:

1. During the rupture chorionic elements may have been "sprayed" over the surrounding parts, especially the right broad ligament and the pouch of Douglas. These underwent malignant degeneration later.

2. Chorionic carcinoma may have begun to develop before the actual rupture took place, with the result that malignant cells were directly spread over the broad ligament and Douglas's pouch.

3. This type of growth extends via the veins. Although scattering of malignant cells may not have taken place, the veins of the broad ligament may nevertheless have been packed with syncytial and Langhans's cells spreading in all directions. These would have gone on proliferating after removal of the ruptured ectopic gestation. An earlier stage of this condition would appear to have been present in Hartz's case.

Lastly, the interesting question arises as to the "receptive," or perhaps I should say "resistive," qualities of the pelvic peritoneum in a condition of this sort. We know that the pelvic peritoneum is far more resistant to infection than that of the upper abdomen. But the pelvic peritoneum during the period of pregnancy is not in quite the same condition as it is in the non-pregnant state. There is a much increased blood supply, and all the pelvic organs are in a much more "luscious" condition. May it not, therefore, on this account provide a more "receptive" nidus for the malignant cells showered over it?

According to S. J. J. Leroux (*Thèse de Paris*, 1934, No. 307) undulant fever is not uncommon in Paris, but often escapes recognition. It is usually contracted by slaughterers and butchers who come in contact with sheep from the Mediterranean district. The other chief sources of contamination are raw goat's milk and cheese. Undulant fever in Paris does not assume any special clinical form, but complications are rare and the prospect of recovery is excellent. As regards treatment, novarsenol, vaccine treatment, and microbial extracts in the form of melitin, endoprotein, or endoglobulin prepared from *Br. abortus* should be employed. Prophylaxis should be carried out by vaccination in infected areas, boiling the milk, and the creation of co-operative stores for the sale of milk and cheese with a sanitary guarantee. The thesis contains the histories of twenty cases in patients aged from 10 to 49.

A CASE OF EPIDURAL SPINAL ABSCESS

BY

J. MINTZMAN, F.R.C.S.

Further to the article on acute epidural abscess by Leonard Abrahamson, A. A. McConnell, and G. R. Wilson (*Journal*, June 23rd, p. 1114), I present below the record of a recent case of acute osteomyelitis of spine with epidural abscess. These cases are fairly rare, and very few are published in the British literature.

Case Record

History.—Mrs. B., aged 38, complained of pain in the middle of the back on November 19th, 1932. The pain increased in severity during the following day. On the first day of the illness she had a temperature of 100° F., becoming normal on the third day. Pain in the back continued. On the third day of her illness she started vomiting, which continued for three days. She also complained of very severe bitemporal headache. She was admitted to the National Hospital, Queen Square, under Dr. Gordon Holmes, on November 28th. Her past history was good, but there had been a boil on her chin three weeks before admission.

Examination.—Speech and all cerebral functions were normal, as were all cranial nerves. There was slight but definite pallor of the left optic disk; the right appeared normal. No diplopia, ptosis, strabismus, or exophthalmos. The motor system was normal as regards the upper limbs and trunk, but the patient appeared unable to sit upright without the use of the arms. Motor power was quite good on both sides in the lower limbs. There was disinclination to exercise full motor power in either limb. Reflexes: biceps-jerk, triceps-jerk, and supinator-jerk present right and left. Upper and lower abdominal reflexes absent. Knee- and ankle-jerks present. Plantar extensor on both sides. No signs of meningeal irritation. Sensation appeared to be normal when tested on admission. Vibration, which was faintly appreciated in both lower limbs, was perhaps slightly more obvious on the right side; it was only faintly appreciated below the tenth dorsal spine.

Progress.—On November 29th the condition of spastic paraplegia, which was present on the previous day, had changed into a marked partial paraplegia of a flaccid type, but with preservation of deep reflexes, which were not accentuated. The right plantar was now extensor and the left flexor. Abdominal reflexes had now disappeared. The intercostal muscles below the ninth on the left side were not contracting, and there was present a relatively sensitive level for pinprick and for vibration at the ninth dorsal nerve segment. Some sensation to pinprick was preserved in the legs. The abdominal muscles did not contract so forcibly below the umbilicus, and the latter was drawn up 2 cm. upon head-raising. This had increased since the previous night. There was tenderness over the lower thoracic and upper lumbar spines. At a later hour of the same day the patient had a complete paraplegia of the flaccid type, with absence of knee- and ankle-jerks. Plantar reflexes were also absent. Sensory examination showed a relatively sensitive level to light touch at the ninth dorsal nerve segment on the left, 2 in. above the umbilicus, and in the ninth dorsal segment 1 cm. below the umbilicus on the right. There was now an absolute level for sensation to pinprick at the proximal portion of the second lumbar segment, below which pain was not felt on either side, except down a strip in the antero-lateral portion of the left thigh, in which the pain from the prick was referred to the foot, beneath the left great toe. There was an absolute level at the third lumbar segment for sensation to hot and cold, that for the former being 2 in. higher than that for the latter. Sensation for deep pressure was preserved in the left toe, calf, and thigh, and in the right leg at and above the knee only. In each case it seemed more distinct in the left leg. Sense of position was present for coarse movements at the ankle, but was absent in the great toes. Pathological examination: differential blood cell count showed 19,000 leucocytes on November 29th

at 2.30 p.m. Cerebro-spinal fluid: yellow, setting solid; jelly-like coagulum; total protein 4 per cent., cells 3 per c.mm. On culture, no growth in twenty-four hours.

Operation.—On November 29th, at 11.45 p.m., Mr. Julian Taylor removed the laminae from the seventh to twelfth dorsal. Yellow creamy pus coated the dura over this region. The pus seemed to trickle round from the ventral and lateral aspects, and more was collected towards the caudal portions of the exposure. The next day, at 10 a.m., there was feeble movement of the toes of the right foot. The knee-jerks were absent, and the left ankle-jerk was present: plantar reflexors? flexor. There was some degree of appreciation of pinprick over both legs. On December 3rd there was a fair degree of appreciation to pain over the left leg and thigh; there was a slight return of sensation to pinprick in the right leg above the knee. Below the knee the prick was felt only as indefinite touch localized to the right leg. Light touch was not felt in either leg. The patient knew when the left, and perhaps the right, foot was being moved. Otherwise sense of position was entirely absent. Sensation to deep touch was present in both legs, and localized to the proper leg. This was preserved before operation. Reflexes in the legs were absent except for one plantar reflex flicker on the left. A radiogram of the dorsal spine before operation showed no evidence of bone disease. It may be noted that the temperature never rose above 100°, except immediately after operation.

Post-mortem Examination.—The patient died on December 9th. The brain appeared healthy. There was an open laminectomy over the dorsal spine still draining pus. This seemed to be coming from the front of the cord round the left side. On removal of the cord there was evident erosion of the back of the bodies of the first and second lumbar vertebrae. On opening the dura the arachnoid was seen to be infiltrated with purulent lymph over the lumbar enlargement. From pus removed at operation, on November 29th, a heavy growth of *Staphylococcus aureus* was obtained in culture.

Discussion

This patient gave a definite history of a boil on the chin three weeks before the onset of acute osteomyelitis. The boil was not treated by incision. On first examination paraplegia was found to be present, and an acute transverse lesion of the cord was diagnosed, probably myelitis; but the rapid change in the patient's condition led to the conclusion that this was a case of compression of spinal cord. The sensory changes were just as predominant as motor changes. There was improvement after operation, but, as the post-mortem demonstrates, she had a ventral abscess resulting from the disease of the bodies of the vertebrae, and had developed spinal meningitis, which caused her death.

I am grateful to Dr. Gordon Holmes and Dr. Greenfield for their kind permission to publish these notes.

G. Faldella, writing in the July 31st issue of *Riv. di Patol. e Clin. Tuberc.*, maintains that the only truly active and effective method of treating early pulmonary infiltration in its various stages consists in a carefully performed artificial pneumothorax, followed by a good collapse of the lung, continued for a variable time, in different cases, but usually only for a short period. Conservative and expectant treatment, if carried on, under the supervision of a competent physician under conditions of bodily and mental rest in a modern sanatorium, may be reserved for exceptional cases in which the lesion is in the very earliest stage and there are few or no bacilli in the sputum, no haemoptysis, and no signs of intoxication. Owing to the extreme sensitiveness of these infiltrations to stimuli of any kind, it is important to avoid any strain or stimuli of a clinical, climatic, emotional, or other character. Symptomatic remedies may be of value if used carefully. The best treatment for early pulmonary infiltration therefore consists of artificial pneumothorax, a hygienic mode of life, rest, and symptomatic remedies, followed by climatotherapy.

with a clinical picture to which the term "fourth disease" is applicable, and he appears to agree with Rietschel¹ and other authorities (including the reviewer) that what have been described by this title are mostly mild cases of scarlet fever and probably other exanthemata, especially rubella. As regards the dosage of diphtheria antitoxin Professor Friedemann occupies an intermediate position between those who favour comparatively small doses and those who regard enormous quantities as essential. He is sceptical as to the value of antitoxin in diphtheritic paralysis.

The bibliographies appended to the articles of each contributor are of a more international character than those often found in German works of reference. This statement applies particularly to Professor Friedemann's article on diphtheria, in which British and American, French and Scandinavian, as well as German literature receives due acknowledgement. The text is liberally interspersed with photographs, temperature charts, microphotographs, and other illustrations, some of which are in colour. The work as a whole, emanating as it does from the best-known authorities on the subject in Germany and Switzerland, is a valuable addition to the literature of acute infectious diseases.

CLINICAL PATHOLOGY

It is now twenty years since PANTON'S *Clinical Pathology* was first published, and six years since the second edition appeared. Throughout these years the book has been regarded by clinical pathologists as one of the most useful introductions to the subject in the English language. In fact, it may be described as indispensable to any practising clinical pathologist. The new edition,² in which a great deal of the text has been rewritten and rearranged, looks at first sight much like its predecessors, but in reading through the book one notices many changes. Most of these are definite improvements, such as better ways of performing tests or clearer interpretations of the significance of the results. There are, however, some rather antiquated methods which survive the pruning, such as the method of counting leucocytes described on page 39. Many of the tests could be done equally well by other methods, but it has been a good policy to restrict description to reliable methods of which the authors have experience rather than to offer a large number of alternatives.

Having very little to say in criticism of the general method and contents a reviewer may perhaps be allowed to point out certain mistakes in expression which are out of place in a book that has come to be regarded as a standard work. There are many poorly phrased ideas or ambiguous passages, such as the following (p. 52), which we hope will not be noticed across the Channel. "It has been maintained, particularly in France, that the high blood cholesterol is found in patients with gall stones, but *more trustworthy workers* [our italics] have failed to find figures appreciably above the normal in cases with obstructive jaundice." As examples of ambiguity we might draw attention to the following. Writing of pleural effusions the authors say: "Almost any variety of cell may on rare occasions be found in these fluids. The eosinophil cell is exceptionally predominant" (p. 260). Or again, this curious comment on the fractional test meal: "The sole difficulty in the procedure lies in the withdrawal of the test meal, in reality a very simple manœuvre" (p. 350); or this on the bacteriology of the urine: "Pneumococci in the urine are often re-

corded but rarely found" (p. 339). Other hazy sentences are found here and there, except in Section VIII, dealing with histology. Like previous editions the present volume is well illustrated and accurately indexed.

GNOCOCCAL INFECTION

The subtitle of *Gonococcal Infection: Recent Advances in Pathology, Diagnosis and Treatment*, by R. V. STORER,³ is somewhat misleading; the advances may exist in the author's mind, but some of them will be accepted with considerable reserve by venereologists in general. Many of the views expressed—more particularly concerning the prostate and prostatitis—are sound and in accord with accepted principles, but others are frankly heretical; many of the latter are stated as facts, whereas they merely represent the author's opinion. This little book contains far too many errors—such as that one ounce of 1 per cent. potassium permanganate added to two pints of water makes a solution of 1 in 8,000—and the pontifical and dogmatic attitude of the author invites the question, "Who is Dr. Storer, and by what authority does he make these statements?" The answer is not vouchsafed us. There is no index, and, though many names are mentioned, references are few. The general practitioner who shows an "intelligent interest" by reading this book will probably get some severe shocks.

INDUSTRIAL MALADIES

In a graceful preface Dr. S. A. Henry of the Factory Department of the Home Office gives an interesting and informative biographical sketch of the late Sir THOMAS LEGGE, for several years senior medical inspector of factories. It was a disappointment to those who knew him intimately, and had worked with him, also to many medical men who only knew him through his writings, when, in 1926, Legge retired from the Home Office. The circumstance was not without its repercussion, for it left him with an amount of leisure which was foreign to him. He died on May 7th, 1932, at the age of 69. In *Industrial Maladies*⁴ he has left a book which will live. It was a fortunate choice on the part of the Home Secretary and Sir Arthur Whitelegge when, in 1898, Dr. Thomas Legge was appointed the first medical inspector of factories, for the work not only appealed to him, but supplied him with the opportunity of rendering services he loved to give. The occasion was opportune, for there had risen in this country a wave of public opinion and a sympathetic consideration for the health of the working classes. Lead poisoning, phosphorus poisoning in the manufacturing of lucifer matches, and lead poisoning in the manufacture of pottery had just been subjects of departmental inquiry, and had been reported upon to the Home Office, while in 1895 certain occupational diseases had become notifiable. The foundation was thus laid, and upon it Legge reared his stately fabric. One of his helpful contributions to the elucidation of industrial poisoning is the part played by dust inhaled by the respiratory passages as against other possible channels of entrance, such as the alimentary canal and skin. Experience has confirmed the validity of his contention.

Considerable space is given in the treatise to the subject of lead poisoning, and statistics are appropriately applied. A few years ago it was observed that the number of cases

² *Gonococcal Infection. Recent Advances in Pathology, Diagnosis, and Treatment.* By Robert V. Storer, M.R.C.S., L.R.C.P. With Foreword by Kenneth M. Walker, F.R.C.S. London: J. Bale Sons and Danielsson, Ltd. 1934. (Pp. 91, 7s. 6d. net.)

⁴ *Industrial Maladies.* By Sir Thomas Legge, C.B.E., M.D., D.P.H. Edited by S. A. Henry, M.A., M.D., D.P.H., D.T.M. London: H. Milford, Oxford University Press. 1934. (P. 234; 13 figures. 12s. 6d. net.)

¹ *Clinical Pathology.* By P. N. Pantan, M.A., M.B., B.Ch.; and J. R. Marrack, M.A., M.D. Third edition. London: J. and A. Churchill, Ltd. 1931. (Pp. 484; 50 figures, 12 plates (10 coloured). 15s.)

The most important articles in the work, in the reviewer's opinion, are those by Professor Giannazzani on the acute exanthemata and by Professor Friedemann on diphtheria. Unlike many Continental authorities, Professor Giannazzani appears to accept the streptococcal aetiology of scarlet fever, and is convinced of the value of the specific antitoxin, which, however, he regards as unnecessary in the treatment of mild cases. In his description of rubella he emphasizes the close clinical and epidemiological relationship of the exanthem to glandular fever, and classifies them both under the heading of benign lymphoblastoses, in distinction from the malignant leukaemic lymphoblastoses. In spite of an extensive experience of the acute exanthemata he has never met

Clinical Memoranda

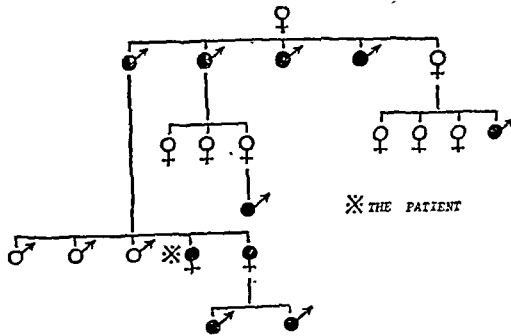

FEMALE "BLEEDERS"

While it is not generally admitted that haemophilia can exist in females, it is certain that there are clinicians who are becoming persuaded that the curt statements to that effect in standard textbooks cannot wholly be justified.

CASE RECORD

The "bleeder" who we briefly discuss here came to us on the third day of her puerperium. A primipara, she had a precipitate labour, and was admitted to hospital after two brisk haemorrhages accompanied by continuous vaginal oozing. A fully trained nurse, she maintained that she was a female haemophilic, and was supported in this statement by her sister, who claimed the same distinction, and was also a nurse. Both came of bleeder stock, as is shown below, and both had had repeated prolonged haemorrhages from trivial causes. Our patient had been in *extremis* on one occasion from tooth extraction. When the occasion arose for her sister to have a major gynaecological operation her assertion that she was a bleeder was wisely confirmed by the finding of a prolonged clotting time, and only minor measures were adopted.

So far as it can be traced the genealogy of these two sisters is as follows:

While one did not wholly accept the stories of our patient and her relative, an examination under gas and oxygen showed that her condition was no ordinary post-partum haemorrhage, the interior of the uterus being perfectly normal for her period of the puerperium. The bleeding was from a serious vaginal laceration, which was oozing from no particular point, and which was mildly septic. This was packed firmly, and a very necessary blood transfusion given with prompt excellent results.

DISCUSSION

Two points may be given particular notice. First, there is the existence of two female bleeders in a known haemophilic family. We use the term "bleeder" in deference to those who maintain that a female haemophilic is beyond reason. That these two might be purpuric is not impossible, but the fact that the two sons of one of them are both haemophilics is suggestive. What may happen to the male child whose birth brought this question to our notice it is yet too soon to predict. The second point is the transmission of a tendency to bleeding to his daughters by a haemophilic male, and those daughters having also the classical taint. It is also worthy of note that the male issue of this haemophilic man is without symptoms, and his sons have had tonsils and adenoids removed without trouble. One uncle of our patient also appears to have transmitted the tendency to a daughter, who is the mother of a definite male bleeder. The least dogmatic authority at our disposal states that a haemophilic man rarely transmits the disease to his sons or the tendency to his daughters. If this is haemophilia it is surely an outstanding example.

M. A. FOULIS, M.D.

J. W. CRAWFORD, M.D.

Glasgow.

Reviews

ACUTE INFECTIOUS DISEASES

An important new work on Acute Infectious Diseases fills the first volume of the Handbook of Internal Medicine, originally edited by Professors Mohr and Staehelin, and now under the editorship of Professors G. von BERGMANN of Berlin and R. STAHELIN of Basle, with the collaboration of Professor von SALLE of Berlin. The whole subject of acute infectious diseases is now contained in a single enormous volume, in contrast with the previous edition, in which it occupied two, each of them more truly deserving the title of handbook than the present somewhat unwieldy tome. The work, which comprises the contributions of seventeen well-known authorities in Germany and Switzerland, deals not only with the acute infections of temperate climates including acute articular rheumatism and miliary tuberculosis, but also with tropical diseases.

The first articles, written by Professor Gustav Liebermeister of Duren, consist of introductory matter and an essay on septicaemia. Among the other contributors are Professor Carl Hegler of Hamburg, co-editor of the second edition of Jochmann's textbook on infectious diseases and author of a monograph (noticed in our issue of May 26th, 1934, p. 950), who writes on acute articular rheumatism, erysipelas, erysipeloid, psittacosis, plague, and tularaemia, and Professor Ulrich Friedemann, formerly head of the department for infectious diseases at the Rudolf Virchow Hospital, Berlin, who contributes an exhaustive and up-to-date article on diphtheria. Professor Eduard Glanzmann of Berne discusses all the acute exanthemata, except small-pox, which is considered by Dr. Albert Eckstein of Düsseldorf; and Professor Alfred Schittenhelm of Kiel contributes the articles on serum sickness, tetanus, dysentery, undulant fever, typhus, Volhynian fever, Haff sickness, and Weil's disease. Professor Felix Lommel of Jena discusses actinomycosis, glanders, foot-and-mouth disease, trichinosis, anthrax, and rabies; and Professor Werner Schultz, who first described agranulocytosis in 1922, has been given the article on the various forms of faucial angina. Professor Rudolf Massini of Basle writes on influenza and herpetic fever, Professor Max Klotz of Lübeck on whooping-cough and mumps, and Professor Morawitz of Leipzig on acute poliomyelitis and cerebro-spinal fever. The contributors to the section on tropical diseases are Professor Carl Hegler and Professor E. G. Nauck of Hamburg, who deal with the various forms of malaria, relapsing fever, rat-bite fever, trypanosomiasis, dengue, Japanese river fever, and yellow fever; Professor Victor Klingmüller of Kiel, who discusses leprosy; and Professors Herbert Elias of Vienna and R. Doerr of Basle, who deal with cholera.

The most important articles in the work, in the reviewer's opinion, are those by Professor Glanzmann on the acute exanthemata and by Professor Friedemann on diphtheria. Unlike many Continental authorities, Professor Glanzmann appears to accept the streptococcal aetiology of scarlet fever, and is convinced of the value of the specific antitoxin, which, however, he regards as unnecessary in the treatment of mild cases. In his description of rubella he emphasizes the close clinical and epidemiological relationship of the exanthem to glandular fever, and classifies them both under the heading of benign lymphoblastoses, in distinction from the malignant leukaemic lymphoblastoses. In spite of an extensive experience of the acute exanthemata he has never met

¹ *Infektionskrankheiten. Handbuch der inneren Medizin. Erster Band. Dritte Auflage. Herausgegeben von G. von Bergmann und R. Staehelin unter Mitwirkung von v. SALLE. Berlin: Julius Springer. 1934. (Pp. xvi + 1,299; illustrated. R.M. 90; geb. R.M. 96.)*

with a clinical picture to which the term "fourth disease" is applicable, and he appears to agree with Rietschel* and other authorities (including the reviewer) that what have been described by this title are mostly mild cases of scarlet fever and probably other exanthemata, especially rubella. As regards the dosage of diphtheria antitoxin Professor Friedemann occupies an intermediate position between those who favour comparatively small doses and those who regard enormous quantities as essential. He is sceptical as to the value of antitoxin in diphtheritic paralysis.

The bibliographies appended to the articles of each contributor are of a more international character than those often found in German works of reference. This statement applies particularly to Professor Friedemann's article on diphtheria, in which British and American, French and Scandinavian, as well as German literature receives due acknowledgement. The text is liberally interspersed with photographs, temperature charts, microphotographs, and other illustrations, some of which are in colour. The work as a whole, emanating as it does from the best-known authorities on the subject in Germany and Switzerland, is a valuable addition to the literature of acute infectious diseases.

CLINICAL PATHOLOGY

It is now twenty years since PANTON's *Clinical Pathology* was first published, and six years since the second edition appeared. Throughout these years the book has been regarded by clinical pathologists as one of the most useful introductions to the subject in the English language. In fact, it may be described as indispensable to any practising clinical pathologist. The new edition,² in which a great deal of the text has been rewritten and rearranged, looks at first sight much like its predecessors, but in reading through the book one notices many changes. Most of these are definite improvements, such as better ways of performing tests or clearer interpretations of the significance of the results. There are, however, some rather antiquated methods which survive the pruning, such as the method of counting leucocytes described on page 39. Many of the tests could be done equally well by other methods, but it has been a good policy to restrict description to reliable methods of which the authors have experience rather than to offer a large number of alternatives.

Having very little to say in criticism of the general method and contents a reviewer may perhaps be allowed to point out certain mistakes in expression which are out of place in a book that has come to be regarded as a standard work. There are many poorly phrased ideas or ambiguous passages, such as the following (p. 52), which we hope will not be noticed across the Channel. "It has been maintained, particularly in France, that the high blood cholesterol is found in patients with gall stones, but *more trustworthy workers* [our italics] have failed to find figures appreciably above the normal in cases with obstructive jaundice." As examples of ambiguity we might draw attention to the following. Writing of pleural effusions the authors say: "Almost any variety of cell may on rare occasions be found in these fluids. The eosinophil cell is exceptionally predominant" (p. 260). Or again, this curious comment on the fractional test meal: "The sole difficulty in the procedure lies in the withdrawal of the test meal, in reality a very simple manoeuvre" (p. 350); or this on the bacteriology of the urine: "Pneumococci in the urine are often re-

corded but rarely found" (p. 339). Other hazy sentences are found here and there, except in Section VIII, dealing with histology. Like previous editions the present volume is well illustrated and accurately indexed.

GONOCOCCAL INFECTION

The subtitle of *Gonococcal Infection: Recent Advances in Pathology, Diagnosis and Treatment*, by R. V. STORER,³ is somewhat misleading; the advances may exist in the author's mind, but some of them will be accepted with considerable reserve by venereologists in general. Many of the views expressed—more particularly concerning the prostate and prostatitis—are sound and in accord with accepted principles, but others are frankly heretical; many of the latter are stated as facts, whereas they merely represent the author's opinion. This little book contains far too many errors—such as that one ounce of 1 per cent. potassium permanganate added to two pints of water makes a solution of 1 in 8,000—and the pontifical and dogmatic attitude of the author invites the question, "Who is Dr. Storer, and by what authority does he make these statements?" The answer is not vouchsafed us. There is no index, and, though many names are mentioned, references are few. The general practitioner who shows an "intelligent interest" by reading this book will probably get some severe shocks.

INDUSTRIAL MALADIES

In a graceful preface Dr. S. A. Henry of the Factory Department of the Home Office gives an interesting and informative biographical sketch of the late Sir THOMAS LEGGE, for several years senior medical inspector of factories. It was a disappointment to those who knew him intimately, and had worked with him, also to many medical men who only knew him through his writings, when, in 1926, Legge retired from the Home Office. The circumstance was not without its repercussion, for it left him with an amount of leisure which was foreign to him. He died on May 7th, 1932, at the age of 69. In *Industrial Maladies* he has left a book which will live. It was a fortunate choice on the part of the Home Secretary and Sir Arthur Whitelegge when, in 1898, Dr. Thomas Legge was appointed the first medical inspector of factories, for the work not only appealed to him, but supplied him with the opportunity of rendering services he loved to give. The occasion was opportune, for there had risen in this country a wave of public opinion and a sympathetic consideration for the health of the working classes. Lead poisoning, phosphorus poisoning in the manufacturing of lucifer matches, and lead poisoning in the manufacture of pottery had just been subjects of departmental inquiry, and had been reported upon to the Home Office, while in 1895 certain occupational diseases had become notifiable. The foundation was thus laid, and upon it Legge reared his stately fabric. One of his helpful contributions to the elucidation of industrial poisoning is the part played by dust inhaled by the respiratory passages as against other possible channels of entrance, such as the alimentary canal and skin. Experience has confirmed the validity of his contention.

Considerable space is given in the treatise to the subject of lead poisoning, and statistics are appropriately applied. A few years ago it was observed that the number of cases

² *Gonococcal Infection. Recent Advances in Pathology, Diagnosis, and Treatment.* By Robert V. Storer, M.R.C.S., L.R.C.P. With Foreword by Kenneth M. Walker, F.R.C.S. London: J. Bale Sons and Danielsson, Ltd. 1934. (Pp. 91. 7s. 6d. net.)

³ *Industrial Maladies.* By Sir Thomas Legge, C.B.E., M.D., D.P.H. Edited by S. A. Henry, M.A., M.D., D.P.H., D.T.M. London: H. Milford, Oxford University Press. 1934. (P. 234; 13 figures. 12s. 6d. net.)

² *Clinical Pathology.* By P. N. Pantan, M.A., M.B., B.Ch.; and J. R. Marrack, M.A., M.D. Third edition. London: J. and A. Churchill, Ltd. 1934. (Pp. 484; 50 figures, 12 plates (10 coloured). 15s.)

of plumbism had increased in house painters. This was followed by a decline, mainly due to the recommendation of C. A. Klein to substitute the "wet" for the "dry" method of rubbing down of painted surfaces. It is not only a satisfaction to observe the reduction of the occupational mortality of lead poisoning generally in this and other countries, but interesting to note the change in the symptomatology of the malady. Lead poisoning has lost much of its severity: its symptoms are milder. Colic with constipation, anaemia, and headache remain the triad of its early symptomatology; wrist-drop follows, as a rule, later, while in one of the acute forms of the toxæmia severe headache, convulsions, and coma seldom occur to-day compared with three decades ago. Contracted kidneys and thickened arteries still remain the final pathological finding in chronic plumbism. Allusion is made in the text to the important research work by Aub and his colleagues in Harvard University, and especially to the circumstance of the metal in the body being transported by the blood stream in the form of colloidal lead phosphate, and of being deposited in the bone tissues as a rather insoluble tertiary lead phosphate.

There is hardly any subject of industrial medicine which is not dealt with in the book. The chapters on metallic poisoning, generally, and the harmful effects of gases, bear evidence of careful preparation, as do also the pages devoted to benzene and its homologues. Such subjects as mule-spinners' cancer, silicosis, and pulmonary asbestosis are also adequately reviewed. Sir Thomas Legge has left a valuable contribution to the subject of occupational maladies. High praise is due to the editor, Dr. S. A. Henry, for the efficient manner in which he has discharged a fraternal task.

MEDICO-LEGAL NECROPSIES

The Medicolegal Necropsy^{*} is an American publication of 167 pages, consisting of an introduction and six papers delivered at a symposium of the American Society of Clinical Pathologists in June, 1933, dealing with the determination of the cause of death in supposedly criminal cases. The collection, which is edited by the chairman of the society's committee on necropsies (who has also written the introduction), includes papers on "The Medical Examiner's Findings in Deaths from Shooting, Stabbing, Cutting, and Asphyxia," by H. S. Martland, the professor of forensic medicine in New York University; "Toxicology in the Medicolegal Necropsy," by Alex O. Gettler, toxicologist to the chief medical examiner's office, New York City; "Pathological Anatomy of Death by Drowning," by E. L. Miloslavich of the Institute of Legal Medicine, Yugoslavia; "The Medicolegal System of the United States," by O. T. Schultz; and two papers on "The Medicolegal Necropsy," by A. V. St. George and Charles Norris, chief medical examiner, New York City. The first forty pages are a condemnation of the coroner system. The evidence brought forward for its abolition and replacement by a medico-legal institute will strike many readers as most convincing, and the statement is made that "the superiority of the medical examiner system in those populous communities where the system has been tried is without question."

The experience of some of the contributors will be realized when it is seen that over two thousand human bodies are analysed annually in Dr. Gettler's department, and that during the five-year period 1928-32 there were 2,457 homicides in New York City. Their conclusions as to the best system to be adopted for carrying out these investigations are not to be lightly put aside. The impor-

tance of a detailed post-mortem examination in cases of fatal street accidents is emphasized by the chief medical examiner, New York City, and is of interest in connexion with the present road safety campaign in this country. He stresses the point that alcoholism, not only of the drivers, but also of pedestrians, is a large causal factor, and states that the statistics of his office show that in nearly 25 per cent. of deaths in street accidents a full post-mortem examination proved the victims to have been drunk at the time of their death. Dr. Miloslavich draws attention to several not widely recognized effects of drowning, especially to haemorrhages in the tissues of the neck, which may lead to an assumption of strangulation; and the last paper, by Professor Martland, which is profusely illustrated, deals shortly with various causes of violent death.

This publication expresses the trend of opinion among workers of enormous experience in this branch of medicine, as to the requirements of a modern community in the investigation of sudden deaths; and, though not containing much scientific detail, it is both stimulating and valuable.

ESSENTIALS OF HISTOLOGY

It is nearly fifty years since Sir E. SHARPEY-SCHAFER'S *Essentials of Histology* first appeared. On its appearance it immediately took its position as the standard textbook of histology for students in this country, and it has maintained that position in the twelve editions that have subsequently appeared. The enormous advances in knowledge and method which have been made in the interval give the recently issued thirteenth edition^{*} the appearance, by comparison, almost of a new work. By those, however, who knew the original, many features, in illustrations, directions, and arrangement, will be recognized, and the characteristic qualities of the work remain unchanged. The editorship of the present edition has been entrusted to Dr. H. M. CARLETON. He has made no considerable changes, but certain portions, such as the sections on the development of blood corpuscles and on ossification, have been rewritten. A number of the older illustrations have been replaced by new figures, mainly photographs of microscopical preparations. Of the figures themselves, with which the book is copiously illustrated, it is impossible to speak too highly.

Notes on Books

In his essay on the Aetiology of Infectious Diseases[†] Dr. RAPPIN, who is honorary professor of the medical school and director of the Pasteur Institute of Nantes, in collaboration with Dr. DOUSSAIN makes a claim on behalf of the old conception of diathesis, constitution, and temperament, which, he maintains, should not be entirely discarded in favour of the exogenous origin of infectious diseases. Instead of the system of the individual being regarded as entirely passive, and being ready to allow micro-organisms from outside to invade it, the view should be held that microbic disease may be the result of a spontaneous deviation of an organic function, the micro-organisms in such cases originating in the system itself.

The little work on *German Medicine*[‡] in the Clio Medica Series has been compiled by Professor WILHELM HABERLING, who occupies the chair of the History of Medicine in the Medical Academy at Düsseldorf. Within a small

^{*} *Essentials of Histology. Descriptive and Practical.* By Sir E. Sharpey-Schafer, F.R.S. Thirteenth edition, edited by H. M. Carleton, M.A., B.Sc., D.Phil. London: Longmans, Green and Co. 1934. (Pp. 618; 721 figures. 15s. net.)

[†] *Considérations sur l'Étiologie des Maladies Infectieuses.* By Dr. Rappin, in collaboration with Dr. Doussain. Nantes: Imprimerie de Bretagne. 1933. (Pp. 136; illustrated.)

[‡] *German Medicine.* By W. Haberling, M.D. Translated by Jules Freund, M.D. New York: Paul B. Hoeber, Inc. 1934. (Pp. 160; 9 figures. 1.50 dollars.)

^{*} *The Medicolegal Necropsy. A Symposium held at the Twelfth Annual Convention of the American Society of Clinical Pathologists at Milwaukee, Wisconsin, June 9th, 1933.* Edited for the Society by Thomas B. Magath. London: Baillière, Tindall and Cox. 1934. (Pp. 167; 59 figures. 11s. 6d.)

compass the book gives an excellent summary of the contributions to medicine by German workers from the earliest times until the present day, special chapters being devoted to German medicine in the Renaissance, with special reference to Paracelsus; the seventeenth century, when the teachings of Paracelsus were further developed in the iatrochemical and iatrophysical schools; the eighteenth century, in which the most prominent representatives were Friedrich Hoffmann, Stahl, Albrecht von Haller, and van Swieten; and modern times. The text is accompanied by portraits of Paracelsus, Haller, Johannes Müller, Schwann, Virchow, Koch, Ehrlich, Roentgen, and von Pettenkofer.

Mr. SIDNEY B. WHIPPLE's book entitled *Noble Experiment* contains the history of the origin and progress of the prohibition movement, for which, as is well known, ex-President Hoover used the term that forms the title of the work. While giving a highly sensational account of the activities of all concerned in the production and supply of illegal liquor, it entirely ignores the hygienic and economic benefits conferred by prohibition, particularly in the early period, when enforcement was more rigorously carried out. The optimistic note upon which the book ends has not been confirmed by the latest information from the United States, according to which there has been an increase in drunkenness, motor accidents, and arrests for crime since the repeal of the Volstead Act.

America under Prohibition.

Preparations and Appliances

CATGUT TUBE CRACKER

Mr. W. R. MACKENZIE, F.C.O.G. (Belfast), writes: To overcome the difficulty of breaking "catgut tubes" and save the risk of tearing gloves I have had made for my own use a breaker which is both practical and satisfactory. It consists of two short tubes, one of which is closed at one end, mounted on curved handles hinged together at the centre, which act "anti-scissor-wise." The end of the catgut tube is placed

in the cracker, the handles squeezed together, thus breaking the glass tube in the middle. The catgut can then be lifted out with dissecting forceps without touching the glass. The great advantage of the instrument is that the catgut tubes are not touched. If they are placed in a basin of lotion they can be scooped up into the cracker and broken with one hand. This cracker has been made for me by John Clarke and Co. (Succrs.), Ltd., 8, Donegall Square West, Belfast.

MASTOID RETRACTOR

Mr. REGINALD H. SMITH, D.L.O. (Manc'ester), writes:

Below is described a mastoid retractor which I have designed and have found useful in practice. The two blades carry five teeth each. Three are for the main or central part of the incision, and the two shorter ones, fitting in the lower part of the incision, are carried on the terminal part of the blade, which is curved inwards. This inward curving of the blades, together with the fact that only three teeth are used for the central part of the incision, prevents the lower end

of the incision being stretched and drawn upwards. The instrument is designed with the object of attaining a more satisfactory and adequate exposure of the mastoid cortex—especially the tip, which frequently offers difficulties when instrumental manipulations have to be made. It has the further advantage of holding itself very securely on the wound, and has no tendency to "jump out" while the operation is in progress. It thus gives easy access to the field of work.

I am indebted to Messrs. Mayer and Phelps for the production of this instrument.

ALLENBURYS' URINACIDOMETER

The "Allenburys" urinacidometer has been designed by Allen and Hanburys Ltd. (Bethnal Green, E.2) in order to provide the physician with means for rapidly determining the pH of urine samples from patients who are on a ketogenic diet. It is based upon the use of coloured charts, the colours of which have been matched against samples of urine tinted with the indicators prescribed, and are examined in the special flat test tubes provided in the set. The outfit is contained in a neat japanned metal box, 7½ in. by 4½ in. by 2½ in.; and its price, complete, is 45s.

MEASUREMENT OF VITAMIN A

The replacement of biological methods of standardization by physical or chemical methods is always desirable; but this is particularly true in the case of vitamins, where the biological methods are expensive both in time and in material, since they involve the special feeding of populations of experimental animals for months.

The estimation of the vitamin A content of liver oils was greatly facilitated by the discovery that the vitamin A potency was proportional to the intensity of blue colour developed on the addition of antimony trichloride. The use of this method, however, involves a certain amount of chemical skill, and even when used correctly it sometimes gives unsatisfactory results. The estimation of vitamin A has now been reduced to extreme simplicity by means of a spectrophotometer designed by Messrs. Adam Hilger (98, King's Road, Camden Town, N.W.1). Vitamin A shows an absorption band at 3280 Å, and the apparatus measures the amount of absorption that occurs at this wave-length. The light that passes through the solution falls on a fluorescent screen, and the image formed thereby is matched against a second image, the intensity of which is varied by means of an adjustable aperture. A scale reading proportional to the concentration of vitamin A is thus obtained. The makers claim that any reasonably intelligent operator without any specialized training can estimate the vitamin A content of a liver oil, since the instrument dispenses with the use of chemical reagents and with the need for colour discrimination.

The instrument provides an interesting example of the way in which the ingenuity of the manufacturer of physical apparatus can provide instruments which act as substitutes for human skill. The biological tests for vitamin A require a wide range of specialized knowledge and experience: even the chemical test requires adequate training in special chemical methods, but with this instrument it is simply necessary to move a lever until two lines of light become equally bright. The price of the instrument is only £35, which is not more than the cost of a few biological estimations of vitamin A.

STATE OF THE PUBLIC HEALTH

SIR GEORGE NEWMAN'S REPORT

The assessment of the health of a nation—as, indeed, of an individual—is attended by obvious difficulties. Health is a condition of balance, an imponderable state, “a kind of temper,” as John Arbuthnot expressed it, “gotten and preserved by a convenient mixture of contraries,” only to be brought within the statistical compass by recording the departures from it. Sir George Newman's annual volume—the sixteenth above his, signature—is entitled *On the State of the Public Health*,¹ but it has to be concerned in the main with the study of sickness, incapacity, and mortality. Only in that way can any standard of health be deduced, and even then the standard is relative and inexact. We have an impression that if there were any practical means, such as a periodical assay of the physique of the individuals composing the nation, of expressing national health in positive, instead of negative, terms, the result would be even more encouraging than the figures and inferences in this document concerning the lessening incidence of certain common diseases.

INFANT AND CHILD MORTALITY

Even on such statistical basis as offers itself, the picture, though not without shadows, is a bright one. The crudest of all measurements is the death rate, and here the death rate for the whole population, the infant and child mortality rates, and the particular death rates for measles, whooping-cough, tuberculosis, diphtheria, scarlet fever, small-pox, and rickets have steadily declined for a generation past. The infant mortality rate is now 64 per 1,000 births registered; in the last pre-war year it was 108. It should be added that the improvement relates principally to infants over 1 month old. During the first month of life the mortality is not much less than it was twenty years ago (32 per 1,000, as against 39). Until the early years of the present century the highest infant mortality, owing to the prevalence of epidemic diarrhoea, was in the July-September quarter. The hottest months levied the greatest toll from infancy; the coldest gave the highest general death rate. This difference has now disappeared, and the July-September quarter gives the lowest death rate for infants, as it does for the rest of the population.

Does the pre-school child show a similar improvement in respect of mortality? A statistical review covering this point, for which Professor Major Greenwood and Dr. Bradford Hill are responsible, is embodied in the report, and shows that in spite of the relative absence of direct action by public health services on behalf of the pre-school child, the greatest improvement in mortality for the past three-quarters of a century has been recorded in the ages 1 to 5 years. With the exception of influenza, all the major causes of death in early childhood show a decline as compared even with the immediate pre-war period. The mortality among adolescents, another relatively neglected class, shows the same trend. It may be noted that tuberculosis, the dominating cause of mortality in adolescence, has receded more markedly among boys than among girls.

One cause of death which reflects itself in the tables both for children and for adolescents is a cause of which Sir George Newman's predecessors cannot have taken much cognizance—namely, road accidents. Out of every 1,000 people who die in this country forty-six reach a violent

end, and a principal cause of deaths attributed to violence is the state of the highway. The number of persons killed on the road last year was 6,498, far exceeding the total of suicides and homicides. Sir George Newman permits himself a little homily to the pedestrian, but it rather misses its mark so far as the young child victims—a very large proportion of the whole—are concerned.

STILL NO EVIDENCE OF WIDESPREAD MALNUTRITION

The conclusion set out in last year's report, that there is no widespread malnutrition in spite of economic and social difficulties, is repeated. Evidence collected from various parts of the country, including the distressed areas, indicates that the health of the unemployed and their dependants is, as a whole, not suffering seriously or generally, though it is evident that some of the unemployed men and many of the women and children in the distressed areas are showing the physical signs of prolonged deprivation. The best that can be said is that it is not a deprivation comparable with that of certain periods of the nineteenth century, thanks to the comprehensive resources of public assistance and mutual aid now existing.

Excerpts are given from the reports of medical officers of health and school medical officers in centres where malnutrition might be expected. We make a few representative quotations:

County of London.—" . . . in view of the fact that the selection of schools and age group was made with the direct purpose of discovering the worst, the percentage of children found to be below par is surprisingly small."

Monmouthshire.—" . . . no increase in malnutrition in the school children."

Nottinghamshire.—" . . . no evidence in this county of any definite deterioration in the nutrition of the elementary school children."

Yorkshire (East Riding).—" . . . no evidence of a lowered standard of nutrition."

Yorkshire (West Riding).—" The bulk of the children may be said to be in a reasonable condition of well-being."

Birmingham.—" . . . the children in the city do not show evidence of that malnutrition which is encountered in those areas of the country which have gone through the long period of depression."

Bristol.—" . . . it cannot be said that malnutrition among school children in the city really exists."

Liverpool.—" . . . it does not appear from the evidence that, taking the children as a whole, there has been any increase in the prevalence of malnutrition."

Manchester.—" Malnutrition and rickets to-day only exist among Manchester school children to half the extent to which they did five years ago."

Newcastle-upon-Tyne.—" . . . our figures show an improvement upon those of 1932 and 1931."

Sheffield.—" . . . no falling off in the nutrition of Sheffield elementary school children in spite of hard times."

An inquiry made by the regional medical staff in April, 1934, told the same story—malnutrition not prominent, widespread, or increasing, chiefly reported from Tyneside and dockyard areas on the north-east seaboard, but even there not affecting more than a small proportion of the adult population, and almost entirely absent from the reports from South Wales. So far as the death rate is any criterion, of the six English and Welsh counties most seriously affected by unemployment and industrial depression in 1933 two had a general death rate actually below the average for the country and in the other counties it was only slightly higher. Of the fourteen county boroughs to which the same description applies, three were below the national average and only two (in Lancashire) markedly above it. The infant death rate, however, in nearly all areas was above the national average, often well above.

¹ *On the State of the Public Health*. Annual Report of the Chief Medical Officer of the Ministry of Health for the Year 1933. (H.M. Stationery Office. 4s. 6d. net.)

The conclusion drawn by Sir George Newman is that for more than twenty years the nutrition of the people has been steadily improving, but the problem which remains is far too complex to solve by a model menu; it calls for still further education of the public in personal health, the understanding of the needs of the body, and the wiser choice of foods.

THE TOLL OF MATERNITY

The curve for puerperal mortality is still slightly in the ascendant. The 1933 figure of 4.51 per 1,000 live births registered is the highest in the table, which goes back to 1911. Up to 1924 the rate rarely exceeded 4 per 1,000; since then it has exceeded it every year. The number of mothers who died as a direct consequence of childbirth was 2,618. These ten years of rising incidence have also been years during which an organized effort has been made to reduce the casualties of maternity. Time must be allowed, of course, before the effect of such efforts can be felt, but it is disappointing to find the number of births dramatically falling year by year—the number in 1933 was only two-thirds of the number in 1913—while the maternal mortality remains obstinately high.

One feature which calls both for hopefulness and for inquiry is the fact that the high rate is not evened out over the whole country. There are certain areas which are chiefly responsible for its continuance over a long period. Sir George Newman blacklists thirty-six areas which have had for ten years past an average maternal mortality of above 5 per 1,000 births. Certain Welsh counties and Lancashire boroughs lead the way. "Is it asking too much," he says, "of the authorities responsible for the health governance of these thirty-six sanitary districts to call for a report of this high maternal death rate (if they have not already done so), and then give careful consideration to its contents?" As a contrast he gives the figures for a number of institutions dealing with many thousands of lying-in cases, where the average maternal mortality for ten years has never reached 2 per 1,000. Among 600,000 district midwifery cases of the Queen's Institute of District Nursing the average maternal mortality for ten years has been 1.91.

The continuing high death rate can be assigned to several causes. Inquiries into the deaths of women in childbirth during 1933 showed that in 23 per cent. of them the absence of effective ante-natal supervision contributed to the fatal issue. The ante-natal clinics are insufficiently used, according to Sir George Newman; advice by practitioners is not given as commonly and as customarily as it should be, and in many cases the ante-natal supervision in clinics, in hospital, and in private practice is at present perfunctory, unskilled, or incomplete. Another factor is the neglect of the nutrition of the mother during pregnancy, and yet another, too much or untimely intervention.

ABORTION: CONTRACEPTION

In connexion with the figures for maternal mortality one point which seems rather important is made, not in the report before us, but in the recently issued annual report of the London County Council.² The maternal mortality rate is arrived at by dividing the number of registered births (580,413 in England and Wales in 1933) into the number of deaths recorded as due to pregnancy and parturition (2,618 in that year), giving the figure of 4.51 per 1,000. But whereas in the total of deaths those from miscarriage and abortion are included, the total number of miscarriages and abortions among which these deaths occurred is not added to the total of births. The

births necessarily in general relate to pregnancies of more than twenty-eight weeks' gestation, but the deaths also include those occurring before the twenty-eighth week, and consequently all abortions, even of single women, of which latter a far greater proportion are septic than of married women. This does seem to be a point on which some revision of the statistical method is desirable.

In discussing the question of abortion Sir George Newman points out a primary difficulty with which also the new committee set up by the Council of the British Medical Association will be faced—namely, that there is no system of notification of abortion in this country, and statistical information as to an increase in its occurrence is wholly lacking. It has been estimated that about one in seven pregnancies terminates in abortion, but the figures on which the estimate is based cannot be assumed to furnish a true index of frequency. In 1933 the deaths attributed to abortion in England and Wales numbered 463, of which 257 were due to post-abortive sepsis, being 24.2 per cent. of the total deaths from puerperal sepsis; 121 were due to abortion not returned as septic, and eighty-five were classed as criminal abortions (inquest cases), of which in sixty-eight there had been instrumental interference, while three were known to be due to drugs. In addition, ninety-seven deaths were associated with abortion, though not classed to it. Sir George Newman stresses the need for suitable accommodation for cases of abortion.

The report contains a statement which may be regarded as the considered answer of the Ministry of Health to those who urge local authorities to provide facilities for the practice of artificial contraception. The advocacy of indiscriminate and unskilled contraception has substantial disadvantages: organized instruction might become propagandist, and lead to the commercial exploitation of the means, and the means themselves might be deleterious in their social or physical results, and used for selfishness and debasement. It is not the function of an ante-natal centre to give advice with regard to birth control. In exceptional cases, where avoidance of pregnancy seems desirable on medical grounds, the woman attending a centre should be referred for particular advice on birth control to a private practitioner attached to, or recommended by, the centre or to a suitable hospital or clinic. There is no general statutory power enabling a local authority to establish birth control clinics as such. It is admitted, however, that such clinics are attended by many women who are in need of medical or surgical treatment of disease or discomfort, and the report suggests that possibly there is a place for a different kind of institution which would serve as an out-patient gynaecological clinic, where mothers needing advice on physical and health matters might be assisted. Such an institution under proper medical supervision could receive minor gynaecological cases, counsel mothers of subnormal physique or mentality, and give advice on the practice of contraceptive methods when medically needed. That, apparently, is as far as the Ministry will go.

The sections on general epidemiology, on tuberculosis, venereal diseases, and cancer, on the insurance medical service, and on hospital administration must await a later review.

The National Council for the Unmarried Mother and Her Child has issued a fourth edition of its leaflet entitled "A Few Points of the Law of England and Wales relating to Unmarried Mothers and Illegitimate Children." This is a matter on which the advice of medical practitioners is sought from time to time. Copies may be obtained (price 3d.) from the general secretary, Miss Susan Musson, 117, Piccadilly, London, W.1.

DEATH AND THE SURVIVAL OF RIGHTS OF ACTION

A recent change in the general law relating to the survival of rights of action after death is of considerable interest to members of the medical profession. For many centuries the law of England has been that *Actio personalis moritur cum persona*. Broadly speaking, the effect of this maxim was that if the victim of an injury caused by negligence died, whether in consequence of that negligence or from natural causes, his right of action died with him. His personal representatives could not continue a suit pending at the date of death, nor could they commence proceedings thereafter. To this rule an important exception was made by statute in the middle of last century, when, by an Act known as Lord Campbell's Act, it was provided that if death is caused by negligence those who were dependent upon the deceased might sue for compensation. But this right was conferred only upon a limited class of persons—for example, the parent or child of the deceased—and the amount of compensation recoverable had reference to the degree of "dependence." Again, the action must have been brought within one year of the date of death. To take a concrete example. If a patient dies in circumstances which expose the surgeon to an action for malpraxis, the right of action survives (by virtue of Lord Campbell's Act) to the dependants of the deceased.

But the law has now been altered. Not long since the Lord Chancellor appointed a committee, as the result of whose report an Act known as the Law Reform Act, 1934, was passed in July, 1934. It is with only one of the changes made by this Act that we are concerned. An action now lies or can be continued for damages for personal injury caused by negligence, notwithstanding the death of the victim, and whether the death was or was not caused by the negligence complained of. Furthermore, the action may be brought at any time within six years of the date of the injury. This change in the law is fraught with grave consequences to the medical profession. Consider one or two cases which may arise. A patient dies on the operating table. He may have submitted to the operation, knowing that it was his only hope. He may have been the last person in the world to charge the surgeon with negligence; yet the surgeon is exposed for six years to the risk of an action at the suit of those who are interested in the estate of the deceased. They need not even have been in any way related to or dependent upon him! Again, take the case of a patient who, having submitted to treatment or to an operation, subsequently dies as the result of some

supervening injury or disease. The practitioner who attended him remains—for six years—exposed to the risk of an action, albeit the patient himself had no intention of bringing suit and no ground of complaint against his medical adviser. That the legislature had some compunction—some consideration for the living in so extending the right of action on behalf of the dead—is manifest, because the statute does do something to restrict the amount of damages which may be recovered for negligence causing death. Thus the court or a jury may not award exemplary damages; and damages caused to the estate merely as a result of the death are not to be awarded. For example, if an annuitant or a man enjoying a life interest were to die, the resulting loss to his estate must not be considered. On the other hand, a gain to the estate is not to be taken into account, as where, for example, a man dies whose life is insured.

Had Parliament been content to enact that actions pending at the time of a man's decease may be continued for the benefit of those who come after him there might have been little cause to complain. The proceedings would then have been commenced at the instance of the one person who best knew whether he had a righteous claim or not. But now members of the medical and all other professions are exposed to the risk of actions for negligence at the suit of persons to whom they owed no duty, and to whom they never desired to owe any duty. We can only wonder whether the committee which framed the report that has resulted in this change in the law took any of these matters into consideration in the course of its deliberations.

BRIGHT'S DISEASE

It was Bright's genius that recognized kidney disease as the common cause of a number of different disorders in which death occurs under such widely various circumstances as dropsy, acute inflammation, apoplexy, and uraemia, not one of which points evidently to the kidney as its source. And this brilliant generalization is in no way belittled by the fact that we no longer include under the heading of Bright's disease, as in his day, all kidney affections accompanied by oedema and albuminuria, reserving this term now for bilateral haematogenous renal disease caused by infection or damage to the kidneys incurred in their function as excretory organs. Indeed, Bright's original description can be transferred almost unmodified into the textbooks of the present day; and the clinical picture he drew is so true and proportioned that the subsequent hundred years of work and observation have only painted in the detail without essentially altering the broad outlines. Nevertheless, many advances have been made in our knowledge of renal disease, and these upon several lines.

Histological studies from the middle of last century showed that the essential structures of the kidney could be divided into at least three different parts: the capsule

of Bowman surrounding a knot of thin-walled capillaries, and two tubular portions, of which one was obviously secretory in function and supplied by a rich network of capillaries, while the function of the other was as obviously purely to conduct the secretion to the pelvis of the kidney. It was not till much later, however, that there arose the modern conception of nephrons as the units of which the kidney is built up. Each nephron consists of a glomerulus and its attached tubule. The blood supply of the nephron is peculiar in that the afferent artery breaks up into the knot of capillaries impinging into Bowman's capsule, and reunites in an efferent vessel, which breaks up again into capillaries distributed to the secreting tubule. There is thus a double supply of capillaries to each secretory unit. The kidney is, as it were, a composite secretory organ in which each floret of the daisy head has this double capillary supply. Such a conception has brought harmony into the hitherto discordant theories of urinary secretion, and has enabled a modern theory to be enunciated which accords so well with the results obtained in experimental physiology and pathology as to warrant acceptance. According to this theory the soluble and diffusible substances of the blood are filtered off through the thin capillary wall, which holds back only the cells, proteins, and other colloids, and pass into the lumen of the tubule, where an active secretion brings about a reabsorption of enough of those substances which are useful to the body to raise them to a normal threshold value in the blood, allowing the remainder of the glomerular filtrate, together with the excess of water, to pass on into the collecting tubule and pelvis of the kidney, and so eventually to the exterior.

These conceptions of the structure and function of the kidney have contributed largely to a co-ordinated view of what goes wrong in disease, but the most vehement controversies have raged round the interpretation of the histological findings in the diseased kidney, and much haematoxylin has been spilt in trying to elucidate the problems involved. It is obvious that attempts would be made to differentiate lesions of the glomerulus from affections of the tubules, but the pathological classification into glomerular and tubular nephritis was found to have no regular correlation with the clinical condition of the patients before death. The final position reached in studies on these lines was that the kidney consisted of glomeruli, tubules, blood vessels, and interstitial tissue, and that in diseased kidneys all these four elements were affected in greater or less degree; though of course differentiation could be made when affection of one of the four elements predominated. With glomerular destruction a haemorrhagic nephritis with more or less nitrogen retention occurs; with arteriosclerotic changes in the small renal vessels there is early hypertension; and with degeneration affecting mainly the tubules there tends to be oedema and proteinuria without haematuria or hypertension. Various names have been suggested for these groups; Volhard and Fahr's classification into glomerulo-

nephritis, nephrosclerosis, and nephrosis is perhaps as widely accepted as any. The first group includes acute nephritis and latent or progressive chronic nephritis leading to renal failure; the second and third groups correspond roughly with the old classification into chronic interstitial and chronic parenchymatous nephritis respectively.

For years Volhard has held that, in the first group, acute glomerulonephritis starts with a toxic spasm of the glomerular capillaries. Recently, however, it has been possible, as Fahr¹ points out, to produce experimental lesions in rabbits by means of a specific nephrotoxin. The earliest lesion is found to be an endothelial proliferation which precedes the vascular changes; these may be a hyperaemia or an emptying of the capillaries through pressure of exudation rather than a primary vascular spasm. In the chronic stages Volhard assumes that the spasm, at first reversible, becomes fixed by changes due to endarteritis. This endarteritis and necrosis of the arterial wall is not constant, and is more likely the result of the chronic glomerulonephritis, which is kept up by a mild continuous streptococcal infection. Even in the form which is progressive without apparent chronic infection, it is unnecessary to assume the intervention of vascular changes, since once the glomerular epithelium is sensitized it may be damaged further by the excretion of waste products which would not ordinarily affect healthy cells.

The term "nephrosis," introduced in Germany to cover cases of primary degenerative changes in tubules and glomeruli, and accepted in the United States, where many clinical examples have been recorded, has never really been adopted into British medicine. There are certain cases of Bright's disease in which the dominant features are prolonged proteinuria and oedema without accumulation of urea and nitrogenous products in the blood; but the more carefully histological examinations are made the fewer remain in which no glomerular changes can be demonstrated. Professor Shaw Dunn,² in an admirable review of the present state of knowledge of the subject and from his own carefully conducted observations, concludes that in all these cases the primary lesion is in the glomerulus. He further suggests that a mild lesion widespread throughout the glomeruli, causing them to be constantly permeable instead of contracting and dilating at intervals as in health, will best explain the large amount of albuminuria which is combined in these cases with oedema and no retention of nitrogen, since all the damaged glomeruli are constantly patent and allow increased filtrate, while the slow trickle through the tubules consequent upon the absence of hypertension permits of increased reabsorption of salt and water. He regards the accumulation of lipoids in the tubules as entirely secondary, and brought about by the opportunity for increased absorption owing to the sluggish current in the lumen of the tubule. In the other forms of so-called nephrosis, lipoid or amyloid, again the tubular

¹ *Klin. Woch.*, April 28th, 1934, p. 609.

² *Journ. Path. and Bact.*, 1934, xxxix, 1.

accumulations are secondary, and in these cases are due to extrarenal causes; as also is the kidney of pregnancy, in which liver changes are as severe as the renal changes, and probably contribute more to the symptoms. In regard to the third group, it is perhaps too early to decide that cases of nephrosclerosis are to be differentiated entirely from the essential renal lesion underlying Bright's disease. Leading pathologists would appear to be returning to the position taken up by Bright in his celebrated researches—namely, the unity of nephritis as an affection of the essential renal elements. As a river stagnating spreads out through channels and diverticula, these, though meandering, run roughly parallel till they join again into a stream that will bear forward the raft of medical knowledge.

RHEUMATISM AND THE "ACID CHILD"

The acid diathesis of rheumatism is a long-standing theory which is liable to be criticized when the vague general term is applied more particularly to the manifestations of rheumatic infection in childhood. An attempt to divide children into "acid" and "alkaline" types in a textbook¹ some years ago had an unpopular reception, and the suggestion that the rheumatic child fell into the first group was countered by Professor Leonard Parsons with a report² showing that examination of the hydrogen-ion concentration of the blood, for example, demonstrated no significant difference in the rheumatic as compared with the normal child. In the August issue of the *Archives of Disease in Childhood* Dr. W. W. Payne, biochemist at the Hospital for Sick Children, Great Ormond Street, attacks the problem in another way. He points out that in a normal functioning body the blood may very well fail to show changes in the acid-base regulation owing to the efficiency of the excretory organs. Of these the kidney is the most important, so that an examination of the acid output might reveal differences impossible to detect in the blood. The method adopted in testing this hypothesis was to take a group of about 200 children attending a "rheumatic clinic" and two control groups—one attending an "asthma clinic" and one of healthy children in a residential school. It was unfortunately not possible to secure a strictly comparable group of healthy children attending hospital, but Dr. Payne brings forward strong arguments to support his acceptance of the residential school children as strictly normal and comparable. Three specimens of urine were obtained from each child—that passed on rising, after breakfast, and on going to bed. The chemical examination included estimation of the hydrogen-ion concentration, free acid, ammonia, chlorides, phosphates, and urea. The methods used for expressing the results have been chosen to get over the difficulties of the large number of uncontrolled factors which can influence the fluid excretion of the body. By frequency curves and by a statistical analysis of the figures obtained it is shown that the asthmatic and rheumatic groups both

differ from the controls. For free acid the two former groups show a significant excess over the normal; there is the same excess of total acid, while the normals also excreted less phosphate. Other minor differences are also present, all tending to indicate a real excess of acid excretion by the rheumatic and asthmatic groups. Unknown to Dr. Payne the latter group were all receiving hydrochloric acid as part of their treatment (1½ drachms daily in most instances). When a deduction is made from this in the results obtained the asthmatic group approaches very closely to the normal group as regards the excretion of acid, a point used to emphasize that the institutional children may be fairly used as controls. From the results obtained it would appear that Dr. Payne's hypothesis has been substantiated. He concludes that the rheumatic child in a quiescent interval excretes more acid in its urine than does either an asthmatic or a normal child. This excess production of acid is insufficient to disturb the equilibrium of the blood.

CHEESE-PARING AT GENEVA

The penny-wise people who have been so active in the League of Nations these last few years (writes our Geneva correspondent) have had their way, and it is an impoverished organization and depleted staff which waits upon the fifteenth Assembly. No fewer than fifty-eight posts in the Secretariat, out of six hundred or so, have been suppressed, at an annual saving of 500,000 Swiss francs, and the budget for 1935 is down by a corresponding amount. Despite this large reduction of staff, entailing the disappearance of some high officials who have been with the League since its beginning, we are assured that efficiency—blessed word!—has been maintained. The expenditure on the International Health Organization is only two-thirds of what it was in 1931, and it is frankly stated that any further reduction in its budget can only be obtained by serious curtailment of fundamental activities. But still the economizers—chiefly delegates from the British and Dominion Governments, for the Continental mind seems to be more emancipated in this respect—remain on the warpath. Politicians who in their own parliaments vote for a new battleship without a blush are querying at Geneva the cost of repairs to a chimney flue or the family allowance of a clerk. To judge from some expressions of imperial opinion at the present Assembly, the most magnificent contribution which the League could make towards peace would be to reduce its annual expenditure on that object. International good will, apparently, is worthy of lip service, but not of any odd change that happens to be in the pocket. The actual figures ought to be stated as baldly as possible. The total expenditure of the League as estimated for 1935 is, roughly, 30 million Swiss francs, or, at the present low value of the pound, £2,000,000 sterling, and of this amount the United Kingdom pays one-ninth. All the fuss and fury of a certain section of English opinion over the extravagance of Geneva concerns a matter of a quarter of a million pounds, or an annual tax of something like one penny farthing on each British citizen. Taking the International Health Organization alone, which is a field where the League might expect to have no critics, except those who urge it on to bigger endeavour, the total expenditure for

¹ *Recent Advances in Diseases of Children*. By W. J. Pearson and W. G. Wyllie. First edition.
² *Arch. Dis. in Child.*, 1926, iv, 291.

1934 was 1,650,000 Swiss francs; and for 1935 the estimate is 1,185,000, the chief savings being on the work of the technical committees, the experts, the collective and individual studies, and the contribution to the Singapore bureau. The amount mentioned includes grants from the Rockefeller Foundation, with the result that the net expenditure chargeable to the League for international health work for 1935 is only some 800,000 Swiss francs, or about £50,000, of which the British contribution is equal to the salary of a Cabinet Minister. For this modest sum many expert inquiries are set on foot, a service of epidemiological intelligence is undertaken, missions to parts of the world where public health is backward are conducted, and the system of liaison between the various health services is maintained. The Rockefeller Foundation provides the salary of the chief of the epidemiological service and of fourteen other officials. It is certainly a little depressing to hear the Secretary-General declare apologetically that since 1932 the budget for these and other League services has been progressively reduced, and still more melancholy to find the delegates, instead of rising up in wrath, accepting the fact complacently as a tribute to the business acumen of themselves and their predecessors.

A METABOLIC EXERCISE TOLERANCE TEST

S. Soskin, L. N. Katz, *et al*¹ describe a simplified method of determining the excess oxygen consumption during exercise and the time required for recovery by the metabolic exercise tolerance test. It permits a visual check on the steady state of the patient before the exercise, and his return to the resting level after it. The simplified method is hardly more difficult to perform than the ordinary basal metabolism test when the equipment has been assembled, and in this form it is suitable for routine use in the clinical laboratory. The objective nature of the test, eliminating the subjective influences of both patient and physician, renders it suitable for comparative work by different groups of observers, and applicable to the classification of cardiac disability for insurance purposes. In a second contribution² the authors record the results of applying this test to a group of patients with cardiac disease. It was found that the measurements, particularly of the excess oxygen consumption during exercise, were greater than normal in patients with organic heart disease and with a history of some limitation of activity, even when no congestive heart failure was present. When these patients were classified into subgroups according to the history of the degree of limitation of activity, the measurements became progressively greater as one passed from the group with no limitation of activity to the group with marked limitation. It is concluded, therefore, that this test, which yields an objective quantitative estimation of the cardiac capacity of a patient at the time of examination, merits further consideration as an adjunct in the study of cardiac disease, and affords material for determining prognosis and treatment. A series of tests is in progress on patients developing and recovering from congestive heart failure, and on patients with reactivation of rheumatic infection, in order to correlate more closely the results of the test with the condition of the patient at the time of the

test. The investigations have already made it clear that both healthy and diseased patients show a considerable variability in their response to the test in short periods of time, but that such variability has well-defined limits in each case. It is suggested that such individual variations have been overlooked in previous estimations of capacity, and that this accounts for discrepancies in reports by different series of investigators.

CASE MORTALITY OF DIPHTHERIA

It is well known that the case mortality of diphtheria in some areas has risen in late years, and the full explanation is not obvious. D. T. Robinson and F. N. Marshall,¹ in Manchester, have inquired whether the "gravis" and "intermediate" types of diphtheria bacilli cause an unduly high death rate. They found no difficulty in dividing four to five hundred strains into the gravis, intermediate, and mitis groups of J. S. Anderson² and co-workers, though, like some other pathologists, they found variations within the groups. Thus only two-thirds of 127 gravis strains were non-haemolytic, and one-quarter failed to produce the typical early alkaline reversal in broth. By agglutination, Miss Ewing³ could define several starch-fermenting types, none of the types appearing among fifty non-fermenting strains. The dangerous infections with gravis and intermediate strains were found in about 78 per cent. of Manchester patients with death rates of 14 and 16 per cent., while the mitis, present in about one-sixth of the infections, caused a death rate of only 3 per cent. McLeod's collected figures from 2,000 cases show corresponding death rates of 14, 10, and 3 per cent., while Mair and Joe⁴ in 152 London cases found death rates of 11, 8, and 6. Evidence is therefore accumulating in support of McLeod's hypothesis that "mitis" does cause a "milder" infection, at least in the districts from which he gathered strains. It seems that the prevalence of types is changing in places, for Dudley and Parish meet with typical starch-fermenting (gravis) strains more often now in London patients than a few years ago, and of sixty strains tested about 1923⁵ only two fermented starch. Robinson and Marshall think that ordinary antitoxin is more effective against mitis infections: about 70 per cent. of the deaths in the gravis group occurred in patients treated within three to four days of infection. Not all writers would agree with these workers in calling this "early" serum therapy, for, while Cobbett⁶ in an analysis of some 4,000 cases collected over many years found a case mortality of *nil* among persons treated on the first day, the figure for the third day was 11, and for the fourth 17—figures not widely different from those found by the Leeds workers. Parish, Whatley, and O'Brien⁷ injected large amounts of toxin or culture of gravis and mitis strains into guinea-pigs and gave ordinary antitoxin at intervals thereafter. Antitoxin given two hours after infection saved all animals; after eight hours it saved none. In the intervening periods there was no signi-

ficant difference between the percentages saved in the gravis and the mitis groups of animals. Long clinical experience strongly indicates that all diphtheria infections are fundamentally similar, for there is apparently no instance on record in any part of the world in which prophylactic doses of ordinary antitoxin have failed to give complete and immediate protection. A further attempt to explain the high death rates recently recorded led to the suggestion that sera of low "avidity"—that is, low readiness to combine with and neutralize toxin—may be at fault. W. Kolle and R. Prigge* have recently examined the point and give no support to this view: they stress the effectiveness of serum in the early stages of infection. Robinson and Marshall suggest that the ordinary Schick-negative level of immunity affords complete protection against the attack of mitis strains, but not always against gravis or intermediate strains, for they record one severe and three moderately severe infections in children with a "Schick-negative" reaction; presumably the level of antitoxin in the blood of the patients was not determined. Parish (loc. cit.) found that three-score Schick-negative guinea-pigs suffered no harm from the injection of lethal doses of a number of different strains of gravis. Robinson and Marshall inquired whether the infection of the organs and heart blood after death could be detected less commonly in animals injected with mitis strains: mitis was found in pleural fluid or heart blood in about 25 per cent., while the other two types were found approximately twice as often. No observations of the kind relating to human subjects appear to have been made. The average reader, after reflecting on all this puzzling evidence, will again ask how it comes about that, despite the high hopes that insurance practice would offer great opportunity for improvement in early diagnosis and treatment, so many unfortunate children are submitted for serum treatment three, four, or more days after the beginning of the attack. Can our magnificent health organization do nothing by popular education of patients, and by appeals to doctors, to end this reproach?

OPIUM AND THE LEAGUE OF NATIONS: A NEW SOURCE OF MORPHINE

The last report of the Advisory Committee on Traffic in Opium and Other Dangerous Drugs presented to the Council of the League of Nations surveys the present position of the problem as regards both licit and illicit traffic in narcotics. The committee has been strengthened by the addition of representatives of Canada, Persia, Sweden, and Turkey to its membership; Mr. L. A. Lyall, chairman of the Central Opium Board, has been reappointed as assessor, along with M. de Myttenaere, a Belgian pharmacologist of repute. Shrinkage of the licit commerce, under international conventions, and the serious increase of illicit production and traffic in China and Manchuria, as well as in Bulgaria, are the notable features of the committee's survey. While the average annual production of raw opium in the world, apart from China, is stated to be 1,770 tons, the total production in China in 1930 was estimated to be 12,000 tons, or seven times that of the rest of the world. In Bulgaria, according to the Canadian representative, the production of raw opium

is reported to have increased from 4,000 kilos in 1932 to 65,000 kilos in 1934. From the quantities of acetic anhydride imported into Bulgaria, presumably for the manufacture of heroin, it was estimated by the American representative that some 3,000 to 6,000 kilos of this alkaloid were produced in clandestine Bulgarian factories in 1933, or from two to four times the legitimate heroin requirements of the whole world. In Manchuria the introduction of a monopoly system has proved unsatisfactory. In the northern part of the country the production of opium has got out of Government control. It is estimated that no less than 30 per cent. of the population of Manchuria are addicts, while opium shops and smoking establishments abound. A novel and disturbing element in the opium problem is the discovery, made by a Hungarian chemist, that morphine can be manufactured from the dry parts of the poppy plant (straw and chaff) remaining after the ripe capsules have been extracted. These parts have hitherto been treated as useless refuse, and either destroyed or used as manure. The new process has been exploited by the Alkaloida Co., Ltd., in which the Hungarian Government has a controlling interest. There are some 8,000 hectares of land under poppy cultivation in Hungary, and the produce of this poppy straw is estimated at about 13,000 tons in a year. From a ton of poppy straw some 800 grams of morphine base and 80 grams of codeine base can be obtained; it is estimated that this year about 480 kilos of morphine will be thus produced. The Advisory Committee is concerned at the effect which this new source of opium alkaloids may have on the world market; it instructed the secretariat to study the legal and practical aspects of the utilization of this new raw material, and resolved to go more fully into the whole question at its next session.

THE MEDICAL REGISTER: UNTRACEABLE PRACTITIONERS

We publish in the *Supplement* this week, at the request of the Registrar of the General Medical Council, a list of the names of those medical practitioners who have not replied to his inquiries as to the accuracy of their postal addresses. Any practitioner, wherever resident, whose name is included in this list should communicate at once with the Registrar of the General Medical Council, 44, Hallam Street, Portland Place, London, W.1, or, in certain specified cases, with the Registrar of the Scottish Branch Council, 12, Queen Street, Edinburgh, 2.

On November 25th, 1884, the first operation for the removal of a cerebral tumour was performed in the Hospital for Epilepsy and Paralysis (then in Portland Terrace, Regent's Park) by Mr. Rickman John Godlee, afterwards Sir Rickman Godlee, Bt., P.R.C.S. It is proposed to celebrate this jubilee by a paper to be read by Mr. Wilfred Trotter, F.R.S., at the Royal Society of Medicine, and by a commemoration dinner.

By an Order of the Committee of Privy Council the Marquess of Linlithgow is appointed a member of the Medical Research Council on the retirement of Viscount D'Abernon, whom he will succeed as chairman.

THE BRITISH PHARMACEUTICAL CODEX

A SURVEY OF MATERIA MEDICA

We welcome the publication to-day of the fourth edition of the *British Pharmaceutical Codex*.¹ This is one of the most useful reference books available to the medical profession, and our gratitude is due to the Codex Committee of the Pharmaceutical Society for providing an authoritative account of the majority of the drugs used in medicine. Eleven years have passed since the last edition appeared, and the dates of the three previous issues are 1907, 1911, and 1923. Inspection of the volume will explain these relatively long intervals: it is a work whose revision must entail an enormous amount of labour. A comparison of the new edition with that of 1923 shows that the size, form, and general arrangement of the book have not changed greatly, but on closer examination it is evident that the material has been almost wholly rewritten. A large amount of new information has been introduced, and the size has been kept constant by a careful editing of the old material. The scope of the revision can be indicated by the analysis of a typical section—namely, the monographs on sodium salts: in the last edition there were forty-three of these monographs and they occupied forty-four pages, while in the new edition there are thirty-six monographs, which occupy forty-one pages. These figures do not, however, indicate the amount of change, since thirteen of the old monographs have been discarded and six new ones introduced. Moreover, the monographs retained have been rewritten.

The first essential for a work of reference is that it should be up to date, and the new *B.P.C.* is completely satisfactory in this respect. For example, monographs on the following subjects are included: solution of vitamin A, vitamin B concentrates, vitamin C concentrates, cortin, corpus luteum, oestrin, parathyroid extract, and extract of the anterior lobe of the pituitary.

STANDARDS FOR NON-OFFICIAL MEDICAMENTS

The extensive revision the *Codex* has undergone has been accompanied by a certain change in the character of the book. The original purpose of the *Codex* was to provide information concerning all drugs and medicines in common use throughout the British Empire, and to serve as an imperial dispensatory for medical practitioners and pharmacists. Experience has shown, however, the urgent need for authoritative standards for the composition of medicaments which are not included in the *British Pharmacopoeia*, and the new volume devotes a large amount of space to the provision of such standards. In the case of substances included in the *Pharmacopoeia* a brief reference is made to the standards there laid down, but in other cases standards have been devised where this is possible. The provision of standards for a wide range of drugs that are outside the *Pharmacopoeia* is an important public service. The editors explain in the preface that whereas the Food and Drugs Act requires a drug to be of the nature, substance, and quality demanded by the purchaser, yet no legal standards have ever been provided. In practice the courts have used the *British Pharmacopoeia* as a presumptive legal standard, but there has been a need for standards for drugs not included in the *Pharmacopoeia*, and these are provided by the new edition of the *Codex*. The setting up of these standards has raised certain interesting problems; thus the editors have worked out a new and ingenious method for the quantitative measurement of the number of foreign particles present in powdered vegetable drugs.

A new feature of the *Codex* is a short but important section providing standards for surgical dressings. For example, it states limits for the amounts of medicament that should be contained in such preparations as mercury and zinc cyanide gauze, iodoform gauze, boric lint, capsicum wool, zinc oxide plaster, etc. The importance of having some uniform standard for such substances is obvious.

¹ The *British Pharmaceutical Codex*, 1934. Fourth edition. London: The Pharmaceutical Press, 1934. (Pp. 1,768. 35s. net, inland postage 1s.)

This provision of standards is one of the most important functions of the *Codex* so far as pharmacists and chemical manufacturers are concerned, while from the point of view of the medical profession the special value of the *Codex* is that it furnishes information about a much wider range of drugs than those included in the *Pharmacopoeia*. The difference in scope of the two volumes can be illustrated by a simple example. The titles of four successive monographs in the *Codex* are hexamine, hexyl-resorcinol, hirudo, and holarrhena. Hexamine is in both the *Pharmacopoeia* and the *Codex*, hexyl-resorcinol is a synthetic drug which has not been admitted to the *Pharmacopoeia*, hirudo (the leech) disappeared from the last edition of the *Pharmacopoeia*, whilst holarrhena is an old-standing Indian remedy for dysentery which has never been included in the *Pharmacopoeia*.

PHARMACOLOGICAL AND THERAPEUTIC ACTIONS

Another important difference between the *Pharmacopoeia* and the *Codex* is that the former confines itself to laying down standards for drugs, whereas the *Codex* in addition gives information about their pharmacological and therapeutic actions. This feature makes the *Codex* very valuable to medical practitioners, but it has involved the editors in the difficult task of reconciling therapeutic customs with known scientific facts. The compromise adopted has been to list the preparations actually in frequent use, and at the same time to indicate their probable value. For example, eight preparations of dilute hypophosphorous acid are described, whilst under the heading "Actions and Uses" is the simple statement: "There is no pharmacological evidence that they (hypophosphites) behave differently from other inorganic salts, and any benefit derived is ascribed to the iron or calcium with which the acid may be combined." Similarly, two varieties of parathyroid tablets are described, but the reader is warned that this preparation is of little value when taken by mouth. There are also monographs on eight lithium salts; but in each case it is pointed out that the action is essentially the same as that of sodium or potassium salts. The attitude adopted seems a reasonable compromise, but it is important to realize that the *Codex* simply describes what the medical profession prescribes, and does not reject any substance in common use merely because there is no rational foundation for such usage.

A THOUSAND STANDARD PRESCRIPTIONS

The monographs on drugs and on dressings occupy two-thirds of the volume, while the formulary occupies more than half of the remainder. This formulary contains about 1,000 standard prescriptions. Not only is the prescription given, but, where necessary, notes on dispensing are added, and in all cases standards for the resulting mixture are given. In this section regard is paid to elegance rather than to economy. Prescriptions with more than twelve ingredients are not uncommon, and a link with the past is preserved by the inclusion of the antiperiodic tincture, which, with its nineteen ingredients, is a lineal descendant of the theriac or treacles of the Middle Ages. The insurance practitioner who followed these models would, however, probably get into difficulties with the local Panel Committee, and it seems a pity that simpler if less interesting prescriptions have not been included. For example, a formula that will provide a satisfactory emulsion of liquid paraffin and agar is often required, but the one included in the *Codex* contains nine ingredients, and it seems probable that a simpler formula could be devised. The *Codex* would certainly perform a useful service if, in addition to the elegant formulae set out, which often contain half a dozen different flavouring agents, the editors would also give a parallel series of utilitarian formulae.

AN INDEX OF PROPRIETARY NAMES

The volume closes with a series of appendices, most of which are concerned with physical and chemical measurements and chemical tests. The appendix headed "Pharmacological Index" might with advantage have been revised somewhat more rigorously. For example,

the list of nerve tonics opens with formic acid, glycerophosphates, and hypophosphites, whereas the monographs on these substances point out that there is no reliable evidence that they have any such action.

The final appendix gives a list of some 800 proprietary trade names of medicinal substances. The editors point out that it has only been possible to include a small fraction of the branded products that are on the market, but inspection shows that most of the best-known substances have been included. Secret remedies naturally do not appear. The list contains two chief classes of names: first, proprietary names of well-known official drugs such as acetyl-salicylic acid, procaine, barbitone, etc., and secondly, important new drugs that are only sold under their proprietary names—for example, plasmoquine, nupercaine, nembutal, evipan, etc.

An index of this kind was introduced into the last edition of the *Codex*, but was then much smaller. The great increase in the size of the index is an indication of the increasing importance in therapeutics of drugs sold under proprietary names. This index is a feature of the *Codex* that will be found of great value by the medical profession, since it provides an easy means of discovering whether some new and unfamiliar name represents a possible therapeutic advance or merely refers to a special brand of some well-known drug.

It is difficult to do justice to a work of reference of this kind in a short review, since the utility of such a volume depends so much on its detailed accuracy. Perusal of the *British Pharmaceutical Codex*, 1934, shows, however, that every effort has been made to bring it completely up to date, and that it represents the skilful accumulation of a vast amount of information of importance alike to the pharmaceutical and to the medical professions.

Ireland

Local Government and Health Legislation

The text of the Local Government Amendment Bill (Irish Free State) (No. 2), which was recently introduced in the Dail, has been published. Until the Bill is discussed it is not quite clear how far it may go. It would appear, however, that it provides, in certain circumstances, for the abolition of the county health boards. This would mean the transfer of medical and other officials to the county councils, and, in some instances, the discontinuance of existing officers. The Bill provides that on the request at any time, whether before or after the passing of the Bill, of a county council the Minister for Local Government and Public Health may make a dividing order: (a) declaring that there shall be as from the commencement of the order a specified number (not less than two) of rural sanitary authorities in such county; (b) specifying the portion of the county which is to be included in and is to constitute such rural sanitary district, and so far as may be requisite, defining the boundaries of each sanitary district; and (c) selecting a day, not less than three months after the date of the order, to be the appointed one for the purpose of the order. The Minister may also, on the request of the council, alter in such manner as shall be specified in the request the numbers of the council. An order made by the Minister shall, without any confirmation from the Oireachtas, come into operation and have effect on and after the first triennial election of members of the council held after the appointed day. When the Minister has made a dividing order, and either or both of the following circumstances exist, he shall make a new division of the county into county electoral areas, and shall so make such divisions that every electoral area is wholly within one or other of the new rural sanitary districts: (a) one or more of the county electoral areas is, at the date of the order, situate partly in another or others of the new

rural sanitary districts; and (b) the Minister has altered the number of members of the county council. Wherever the Minister has made a dividing order the following provisions shall, on and from the appointed day, have effect: (a) the area of the county, which at the date of the order is a rural sanitary district, shall cease to be a rural sanitary district; (b) there shall be constituted in the county the number of rural sanitary districts specified in the order, and each rural sanitary district shall contain that portion of the county specified in the order; (c) the council of the county shall be the sanitary authority for each of the rural districts so considered; (d) each of the rural districts shall be a county health district within the meaning of the principal Act, and shall be called by the name of the "County Health District of . . ." with the addition of the name of the county and such distinguishing name as the Minister shall direct; (e) subject to the provisions of this Act the principal Acts shall apply and have effect in and relative to every rural sanitary district and county health district, as if such district had been constituted by an order made under Subsection (2) of Section 9 of the Act of 1925; (f) if there is a board of public health in and for the county at the date of the order the board shall be dissolved and cease to exist; (g) a scheme shall be prepared and submitted to the Minister for Local Government and Public Health providing for the continuance or discontinuance of the officers of existing boards. The scheme shall provide: (a) for the continuance of an officer in the service of the board of health of one of the new districts, either in the office he held before, or in an analogous office with analogous duties; or (b) for his appointment, according to law and with his consent, to an office in the service of the board of health of a new district; or (c) for his removal from office. Every dispute as to whether an office is analogous to another, or the duties are analogous to those of another office, or the whole of an officer's time is occupied shall be determined by the Minister, whose decision shall be final.

Criticisms of the Clean Milk Bill

The Department of Local Government and Public Health, in reply to criticisms by Dr. J. C. Saunders, Cork county borough medical officer of health, of the Clean Milk Bill, 1934, has issued a memorandum stating that the object of the Bill is to supplement the legislative powers already in existence for safeguarding milk intended for human consumption, so as to enable the recommendations of the Inter-Departmental Committee on the Milk Supply to be carried into effect, in so far as these recommendations are deemed practicable and desirable. In considering the new powers to be acquired it is necessary in the first instance to review the existing statutory provisions dealing with the supervision of the milk supply. These provisions are mainly contained in Section 34 of the Contagious Diseases (Animals) Act, 1878, and empower the Minister for Local Government and Public Health to make orders in regard to: (a) the registration with local authorities of all persons carrying on the trade of cowkeepers, dairymen, or purveyors of milk; (b) the inspection of cattle in dairies and the regulation of lighting, ventilation, cleansing, drainage, and water supply of dairies and cowsheds; (c) the cleanliness of milk stores, milkshops, and of milk vessels; (d) the precautions to be taken for protecting milk against infection or contamination; and (e) the authorization of local authorities to make regulations concerning the foregoing. The objections of Dr. Saunders to the Milk Bill, as set out in his general commentary, were as follows: (1) the difficulty of obtaining convictions for the sale of dirty milk in the absence of a specific definition of dirty milk; (2) the omission of clauses dealing with the fre

quent veterinary inspection of cows, and measures for the eradication of tuberculous cattle; (3) absence of provisions requiring all milk vendors to be licensed; (4) non-recognition of power of extra-territorial inspection of cattle and premises from which milk is supplied in an urban district; and (5) precautions not yet prescribed in regard to the bottling of milk. He recommended that dairy employees committing offences under the Dairy Regulations should be rendered liable to penalty in lieu of the employers. The Department has dealt with Dr. Saunders's objections as follows: (1) As regards the necessity of defining dirty milk, this term is included in the Dairy Produce Act, 1924, which prohibits the supply of dirty milk or cream to a creamery, and it is understood that no difficulty has arisen in securing convictions under that clause. (2) The problem of the eradication of tuberculous cattle is being considered in all its aspects by the Minister for Agriculture, and is expected to be dealt with shortly. (3) Having regard to the proposed licensing under the Act of all milk vendors selling milk of special designations, including pasteurized milk, it has been deemed sufficient to rely on the powers set forth above under Section 34 of the Contagious Diseases (Animals) Act, for the registration of persons carrying on the trade of cowkeepers, dairymen, or purveyors of milk. (4) The Minister is already empowered under Section 19 of the Tuberculosis Provisions (Ireland) Act, 1908, to authorize an urban district council to arrange for the inspection of dairies outside its district from which the local milk supply is delivered. (5) Under Clause (d) Section 34 of the Contagious Diseases (Animals) Act, 1878, the necessary power for the regulation of milk bottling is available, and will be exercised on the revision of Dairies, Cowsheds, and Milkshops (Ireland) Order of 1908. It is also intended, in connexion with the revision of these regulations, to provide for the penalizing of dairy employees committing offences against the regulations.

The Dufferin and Ava Hospital, Belfast

At a recent meeting of the Belfast Board of Guardians the annual report of Dr. S. R. Armstrong, visiting medical officer, was received. The report stated that 325 mothers and 691 infants had been admitted during the year. The death rate amongst the infants was 17 per cent. A great benefit had been bestowed upon all the patients in the Ava Hospital by the general excellence of the arrangements and appointments. The wards were bright, cheerful, and well ventilated. There was an easy access to beautiful balconies, which were sheltered and sunlit all day. The visiting medical officer referred to some of the difficulties which mitigated against a greater success, although their statistics compared very favourably with those of any other hospital. One difficulty was the large number of infants admitted too late in their illness or so hopelessly ill that it was almost impossible to do anything to save their lives. Fourteen infants died within a period measurable by hours from the time of their admission. A second difficulty was that a hospital such as theirs admitted a large number of infants who could not be discharged, as they were from voluntary hospitals, and when they recovered from the acute conditions and were convalescent, required further careful nursing by a mother, and segregation from all other acutely ill infants. Dr. Armstrong's report went on to state that it was obvious that they could not discharge infants who were convalescent but grossly under weight, because an outcry from some quarter would immediately be heard. Yet this was unquestionably the correct procedure. Such infants should be removed from hospital, where the possibilities of fresh contagion so palpably existed. An essential for such infants was the fondling and mothering and individual attention which every baby

had, even in the poorest of proper homes. A further difficulty which only came into prominence when one had to compare statistics with voluntary hospitals was that they must necessarily admit cases which would not be admitted to the latter hospitals. These were the incurable, and he referred especially to infants newly born with gross skeletal defects of the spine, skull, palate, etc., which could not be remedied by operation. From such defects during the past year they had had eight deaths. A solution of some of their difficulties was obvious even before the Ava Hospital plans were completed, but he hesitated to suggest the large expenditure which inclusion in the new building of an infant convalescent department would have necessitated. The report was adopted.

Royal Academy of Medicine in Ireland

At a meeting of the General Council, held in Dublin at the Royal College of Physicians of Ireland on September 21st, the following candidates were duly elected Fellows of the Royal Academy of Medicine in Ireland: James Bell, D.Sc., E. J. Conway, D.Sc., M.B., T. J. O'Connell, M.B., Harry Lee Parker, M.B., J. A. Wallace, M.B.

England and Wales

L.C.C. Lewisham Hospital Extension

Lord Dawson of Penn will open an extension of the London County Council's Lewisham Hospital on Tuesday, October 9th. The extension includes a maternity department, a children's section, and two general wards. The maternity department is situated on the upper and part of the middle floor of the three-storied block, and provides accommodation for sixty-three mothers and forty-five infants. The principle of the small ward has been followed and there is ample provision of single-bedded wards. There are five labour rooms grouped together on the top floor in a projecting wing and thus isolated from the wards. A sterilizing room, sink room, bathrooms for adults and infants, and a premature babies' room with special heating are placed in convenient proximity. The children's section contains thirty-five cots; there are three wards, of which the largest contains twelve cots, and six isolation cubicles. The two general wards with their associated small wards contain sixty-six beds, and the total additional accommodation provided in the extension is 164 beds, which brings the number of beds in the hospital to 747.

Child Welfare in Birmingham

In his annual report for 1933 Dr. H. P. Newsholme, medical officer of health for the city, points out that a most encouraging indication of the improving health in the younger generation is afforded by the steady and marked decrease which is still discernible in the death rate in early childhood. This rate for the age period 1 to 2 years fell from 45.9 per 1,000 in 1912-15 to 14.3 in the years 1931-3, and the corresponding rate for those aged 2 to 5 fell from 12.2 in the first-year period to 3.9 in the second. He remarks that such a fall, accomplished by successive regular steps during successive periods, is obviously not fortuitous, but is a sign that the general and the specific measures of public health, whether of the maternity and child welfare or of other cognate services affecting the young child, are bearing fruit in the most obvious manner. The birth rate continues to fall in the centre and the middle rings of the city. The death rate in the centre wards is still higher than in the outer

wards, a fact probably associated with such environmental factors as overcrowding, less efficient maternal care, and nutritional difficulties associated with poverty. It is largely due to preventable disease. The continued high neo-natal mortality is preventing a further fall in the infant mortality rate. There is, however, a progressive, though small, improvement, possibly related to the better care which is now taken of feeble infants. The loss of life from stillbirths is unabated, and the number of these is actually higher than that of the neo-natal deaths. While a proportion of these must remain inevitable, being associated with gross congenital malformations, it would appear to be deducible that ante-natal care has not yet reached the root of the problem in its extent or its character. In the age group 1 to 5 years pneumonia is the more frequent cause of death, enteritis being relatively unimportant. Statistics indicate that at the beginning of its life a baby runs little more risk of death if living in the central wards of the city than in the outer ring, but between the third and sixth months the effects of a bad environment become increasingly apparent, until, at the age period 9 to 12 months, the mortality is twice as high in the central as in the outer wards. The city council now maintains twenty-eight child welfare centres, and two subsidiary ones. An attendance at these centres of 71 per cent. of the infants born during the year is very satisfactory, and is higher than in previous years. The number of older children attending has also increased. Special efforts have been made to teach housewifery and family budgeting to the younger women. In some areas the fathers have shown special interest in the work of the centres, and fathers' councils or parents' leagues have been formed. Dr. Newsholme suggests that the general standard of ante-natal care at the child welfare centres could be definitely improved by greater co-operation between medical practitioners, institutions, midwives, and patients, but more research is needed for abnormal cases. Many women also fail to come early enough in pregnancy to gain the full advantage of the present state of knowledge. The public health committee has provided ten ante-natal beds in each of the two city maternity homes. Dr. Newsholme emphasizes the importance of rest in the case of postural defects, since most of the children coming to the remedial exercise clinic are suffering from too little rest. Mothers in most cases do not recognize the need of a daily rest for children between the ages of 3 and 5. The experience of this clinic indicates that improvement cannot be expected quickly, but, given sufficient time and conscientiousness on the part of the parents at home, the results are gratifying.

Scotland

Royal Samaritan Hospital, Glasgow

A medical report is published annually by the Royal Samaritan Hospital for Women, Glasgow, containing details of the work and statistical information. In the issue for 1933 it is recorded that during that year the total number of patients dealt with was 2,962; there were 2,638 operations, and the mortality was 1.32 per cent. A list is given of the aetiological factors involved in the production of the pathological lesions encountered. Injury associated with child-bearing was noted in 1,214 cases, and infection so associated in 578. Infection not associated with childbirth was responsible in 369 cases. The figure for new growths was 481, and for errors of development 188. A detailed analysis of the pathological lesions in tabular form shows the average age of the patients in each group, and their relation to such condi-

tions as parity, the number of years since the last pregnancy, if any, the average number of children and miscarriages, and the incidence of operative intervention. Matter of considerable scientific value is thus published. Two new tables appear in the 1933 issue, under the headings respectively of "Symptoms" and "Surgical Procedures." They have been added to convey an idea of the frequency of the different complaints made by patients coming to the institution, and the number of occasions on which various surgical procedures were performed in the course of a single year. From this it appears that the two most common causes bringing patients to the hospital were haemorrhage and bearing-down sensations, each accounting for about 14 per cent. of the whole. Pain on the left side of the abdomen was a primary manifestation in 10 per cent., on the right side in 6.2 per cent., and on the mid-line or bilateral in 5.2 per cent. Pain in the back alone was the cause in 6.6 per cent., while back pain associated with pain in the lower abdomen was noted in 2.9 per cent., most commonly on the left side. Vaginal discharge was similarly concerned in 8.3 per cent., sterility in 5, excessive menstrual bleeding in 5.1, bladder symptoms in 4.3, and symptoms referable to the rectum in 2 per cent. Dilatation of the cervix and curetting of the uterus were performed on 1,119 occasions, trachelorrhaphy on 500, colpo-perineorrhaphy on 338, subtotal hysterectomy on 256, anteversion of the uterus by shortening the round ligaments (various methods) on 218, and tubal insufflation on 205. A brief summary of each of the thirty-nine fatal cases is appended.

Hospital Problems in Dundee

Hospital policy is discussed in some detail in the annual report for 1933 of the public health department of the City of Dundee. Dr. W. L. Burgess, medical officer of health, states in this connexion that the attention of the City Council during the year was mainly directed to reorganizing the various institutions under their own management, the stage not having yet been reached when complete co-operation with the University and with other hospitals would be possible. He attacks the tendency to emphasize unduly the "hospital services" or the "hospital scheme" as though such services or schemes fell outside the general health movement; the effect, he thinks, might easily be that the hospitals would tend to become a separate service not properly linked up with the other medical and allied services. Even in a general health scheme, he adds, it would be perfectly possible for these institutions to retain their voluntary status, character, and traditions. At present there is believed to be a shortage of hospital beds, and the natural tendency is to aim at providing more, but it is essential to be certain first that the available beds are being used to their best advantage. This matter has been carefully considered by the Dundee Council, which has satisfied itself that by administering Maryfield Hospital under the Local Government (Scotland) Act of 1929 instead of under the Poor Law (Scotland) Act of 1845 better use could be made of the beds in that institution. Accordingly, its services are now no longer restricted to persons whose names are on the poor roll, but have been made available for the general public. Whereas formerly at certain seasons the hospital was not in full use, because it was open to only one section of the public, the beds are now being fully utilized all the year round, and thus without the addition of a single bed the hospital accommodation available to the general community has been definitely increased. Again, a vigorous campaign against slums is now in operation and, if brought to a successful issue, will probably permit domiciliary treatment for many who under the present

conditions would have to be dealt with in hospital beds. An extension of the facilities for home nursing might also have a very definite influence on the demand for hospital treatment, and Dr. Burgess is convinced that the expansion of the national health insurance scheme to cover wives, dependants, and all persons in similar circumstances would render the present hospital problem very much less formidable. If medical attention became more easily available, earlier treatment would prevent many cases from reaching the hospital stage. A larger number of patients could be treated at home if certain additional facilities in respect of diagnosis and treatment were placed at the disposal of general practitioners, or at any rate the average stay in hospital could be appreciably shortened. Such facilities might include laboratory assistance, consultations with specialists, and x-ray reports. Until the report is published of the Departmental Committee which is at present considering the whole question of the health services in Scotland, Dr. Burgess thinks it wise to proceed cautiously so as not to prejudice future action.

CORRESPONDENCE

Increased Mortality from Diabetes

SIR,—The interesting letter from Dr. Alex. Fraser (September 22nd, p. 570) affords a possible explanation for a statement recently repeated that the mortality from diabetes has increased since the introduction of treatment by insulin. This statement, to anyone familiar with the treatment of diabetes during the past thirty years, is so astounding as to be incredible. We know that before the introduction of insulin there were really no known cases of recovery from diabetic coma; I can recall two or three instances in the literature and, to the best of my recollection, they were but temporary recoveries followed by death after a very brief period. To-day recovery from diabetic coma is the rule rather than the exception, and there must be many of us who have seen it occur in over a hundred cases. It is perfectly true that we sometimes encounter a case in which coma is already so deep that we fail to save life; it is also true that the careless diabetic patient may have further attacks of coma months or years after discharge from hospital—instances of restoration from coma five or even ten times in the same patient are not difficult to collect. But how is it possible in the face of this one fact, the modern treatment of coma, to suggest that the mortality from diabetes has increased?

The explanation, as Dr. Fraser suggests, lies probably in faulty statistical analysis. Prolonged experience with a diabetic clinic soon establishes the fact that diabetic patients fall into two main groups: (a) children and young adults with severe diabetes, and (b) elderly people with diabetes of milder degree but commonly associated with arterial disease. The former group call for the greater skill on the part of the physician as regards diet and treatment with insulin, but given a reasonable degree of technical competence the results are almost uniformly good, and the prognosis equally so. The latter group frequently require little treatment as far as the diabetes is concerned, but have a prognosis which is chiefly governed by the concurrent arterial disease; it is an every-day experience to see such patients, in whom the diabetes has been effectively controlled for several years, succumb to such diseases as cerebral haemorrhage, cardiac failure, or gangrene secondary to arteritis. It seems very probable that the frequent inclusion of the word "diabetes" on the death certificates of this latter group accounts for the myth that diabetes itself treated on modern lines affords a bad prognosis.—I am, etc.,

London, W.1, Sept. 22nd.

T. IZOD BENNETT.

Preliminary Ligation in Graves's Disease

SIR,—Since last June there has been an interesting exchange of views in the various numbers of the *British Medical Journal* on the subject of preliminary ligation. It is surprising to find the expression of so many diverse opinions. About twelve years ago the pre-operative treatment of Graves's disease was placed upon a firm scientific basis. Since that time the indications for preliminary arterial ligation are few and far between.

It is true, but not universally true, that the patients who derive greatest benefit from ligation belong to precisely the same group as those who respond readily to the administration of iodine. Conversely, if iodine fails it is reasonable to assume that ligation will prove a disappointment. Dogmatism is, however, to be avoided in this as in most other surgical considerations.

After a long experience in an area in which Graves's disease was not uncommon, I have been guided by certain beliefs.

1. In the case of the really bad surgical risk in which adequate and prolonged pre-operative preparation is of no avail, ligation is indicated. The second or third shot sometimes hits the target and the prognosis may become completely changed. Thus ligations, although rarely indicated, may convert a bad surgical risk into a case safe for thyroidectomy when other weapons have failed.

2. A severe reaction sometimes follows ligation or any other procedure. Such a reaction indicates the intolerant condition of the patient, and is a warning to proceed with caution by carefully graded operative measures.

3. In the event of a fatal result following ligation in the serious type of case under review surgery is blameless.

4. It is important to ligate the trunk of the superior thyroid artery after clear exposure. The anterior branch is sometimes mistaken for the main vessel. Additional ligation of both anterior and posterior branches inhibits the collateral circulation from below. Personally I avoid thyroidectomy in a case of uncontrolled hyperthyroidism without a preliminary attempt to obtain control by ligations. We must recognize, however, that the personal factor is of importance.

Each surgeon will obtain the best results by following the path with which he is most familiar, but familiarity with thyroidectomy does not necessarily imply familiarity with the ligation of the isolated thyroid trunk. I have seen Kocher, Mayo, Crile, and many others at home and abroad, including some of your correspondents, operate on cases of severe hyperthyroidism. As a spectator one instinctively felt that if each had operated in precisely the same manner the brilliancy of the results would have been adversely affected.

Preliminary ligation of the inferior vessels, sometimes recommended as a step towards thyroidectomy, is attended by too much disturbance to justify it as a routine. Here again personal factors must be weighed. Some surgeons have perfected their methods of approach and regard ligation of the inferior thyroid artery as a valuable addition to the patient's defence. Finally, may I suggest the retention of the term "Graves's disease" in general discussions on this subject? Knowledge is incomplete until the works of the great Dublin physician are studied and digested.—I am, etc.,

London, W.1, Sept. 24th.

W. I. DE C. WHEELER.

SIR,—In the hands of my teachers, Sir James Berry and Dr. Strickland Goodall, the use of ligation in severe cases of toxic goitre impressed me so much that I practise it also. The recent correspondence on this subject (*Journal*, June 30th, p. 1187; July 14th, p. 84; July 21st, p. 136; July 28th, p. 181; September 22nd, p. 569), in

which I am greatly interested, prompts me to make the following observations.

It is no argument against ligation to say that it has a mortality. I have known two patients with toxic goitre die when being x-rayed, and only the very worst cases come into the tables of cases treated by ligation. In 280 thyroid operations I have lost one patient following a ligation, but I have lost two patients in 100 resections for toxic goitre, and I believe that ligation is the safer procedure when there is any doubt as to the post-operative reaction.

That there is a therapeutic effect following ligation I have not the slightest doubt. I now have a short series of cases whose goitres were highly toxic, very vascular, diffuse, and small, treated by ligation, in stages, of all four arteries. Some were thus treated before we were using preliminary Lugol's iodine solution. The effect of ligation upon these throbbing, purring, and highly vascular glands was very noticeable, and, what is perhaps more important, the relief of the patients which followed. I would refer to just three such cases: those of a plumber, a railway signalman, and a young schoolmistress. Each was a case of highly toxic, very vascular, diffuse goitre, for whom quadruple-stage ligation was performed with such relief that, from being confined to bed for long periods, each patient was able to return to normal employment. These cases have been seen since and have not relapsed, and the thyroids are apparently normal. In the *British Medical Journal* (1926, i, 561) I drew attention to the benefit to be derived from ligation in such cases.

I believe that the inferior is the more effective artery to tie, because it is the artery to the hilum of the gland (cf. renal, etc.), is usually larger than the superior, and, through a small incision behind the sterno-mastoid, its trunk can be secured, well away from, and therefore without interfering with, the gland itself. I recorded these and other observations relating to the thyroid arteries in the *Journal of Anatomy* (1929, lxiv, 50).

While admitting, therefore, that subtotal thyroidectomy is the operation of choice in most cases, I believe that ligation of arteries has a distinct place in the treatment of toxic goitre, and that those surgeons who lack the very extensive clinical and operative experience of Mr. C. A. Joll will do well to apply the maxim: When in doubt ligate.—I am, etc.,

LAMBERT ROGERS.

Medicine, Cardiff, Sept. 24th.

Ether Convulsions

SIR,—The following case serves to strengthen an already strongly held opinion—that gas and oxygen should always replace ether as far as possible, especially in young and septic patients.

On July 28th, 1934, I anaesthetized a male patient, aged about 20, for operation for acute appendicitis. He was of very good physique; it was an emergency case at midnight, so no basal anaesthetic was used: for these two reasons ether was employed. Induction was by ethyl chloride and eau-de-Cologne, followed by closed ether and oxygen. Colour was bright pink throughout. Respiration was somewhat jerky all the time, in spite of nasal and oral tubes, which gave a good airway. Otherwise anaesthesia was without incident until the peritoneum was being sutured. This was after about fifty minutes—the appendix was sloughing, adherent, and difficult to separate, which accounts for the operation taking three times as long as usual.

Twitching movements of the right side of the face were then noticed. The anaesthetic was stopped immediately, as their significance was realized at once owing to experience of a previous case. The twitchings spread over the face, and also affected the body muscles. They continued for five to ten minutes, but never became very severe. Carbon dioxide and

oxygen was given, and the table raised into the head-up position. The movements then stopped. (Raising the head is a method of treatment which appears to have been successful in other cases.) It is an interesting fact that, as far as I know, only one case of chloroform convulsions has been recorded. This is suggestive, in view of the cerebral anaemia produced by chloroform.)

Intravenous barbiturates have been recommended, but no sedative of this sort was available (it was a nursing home case and 1 o'clock in the morning); so a second dose of morphine was given. Uneventful recovery followed.

This case is very typical: young adult, septic case, summer weather—these three factors are almost invariably present. In the *British Medical Journal* (June 21st, 1930), following a previous (fatal) case of ether convulsions, I collected twelve different theories of causation from the literature, none of which fitted the facts. I tentatively suggested a thirteenth—namely, that the convulsions might be due to impurities in the oxygen. Unfortunately the oxygen used in this case could not be tested, because the cylinder ran out just before the onset of the convulsions.

The points of interest in this case are: (a) The convulsions were not severe. Was this due to the stopping of the anaesthetic immediately the first slight facial twitching appeared, or was it just luck? (b) They stopped almost immediately the head was raised. Again, was this *post* or *propter*? (c) As in my only previous case the patient had died on the table it was a very anxious five minutes. Even when the convulsions stopped there was the possibility that they might start again during the next few hours. This has been known to occur. The morphine was given for this reason, and also a supply of carbon dioxide was left by the bedside. (d) Was the jerky respiration, in spite of a good airway, a premonitory sign of the convulsions, or due to the same cause which produced them?—I am, etc.,

Morley, nr. Leeds, Sept. 23rd.

W. STANLEY SYKES.

Control of Treatment in Cancer by Serum Tests

SIR,—Dr. Hernaman-Johnson's letter (September 15th, p. 534), with regard to his employment of the modified Bendien reaction as a means of estimating the response to x-ray treatment in cancer patients, is an interesting and valuable corroboration of my own findings, to which reference has been made in a recent publication on the "Serological Observations from Cases of Cancer under Treatment." From my experience of this test during the past three years, the reaction of the serum in the large majority of cases is positive in those showing active clinical cancer, the exceptions being found in those associated with sepsis or suffering a marked degree of emaciation, and the reasons for the alteration of the usual reactions under these conditions are explained in the paper referred to above. After removal or destruction of the local cancer, the blood serum reaction in the majority of cases still remains positive. In those in which it subsequently has become and remained negative, and regained a normal reaction, recurrence or metastases have not so far developed. In others, whose serum had regained a negative reaction, clinical recurrence has been preceded by the return of a positive serum reaction, and these alterations can be observed and detected by consistent periodic follow-up serum tests such as Drs. Hernaman-Johnson and Harry Coke are adopting.

It is in the group of cases whose serum reaction has remained persistently positive in spite of clinical post-operative improvement that recurrence and metastases have been found to develop most regularly. There is, however, a further group of cases which have now been

watched for periods of two years or more in which the serum reaction remains consistently positive though the primary tube reaction is more or less in the normal zone, and in these so far there has been no evidence of clinical recurrence.

The observations of Lockhart-Mummery and others have given very strong evidence that the local development of cancer depends upon an intrinsic gene instability of the cells affected, producing those mutations which result in dedifferentiation. If surgical treatment has successfully removed all such cells, it is quite feasible that further local cancer will not recur or develop, although the serum reaction of the patient remains positive, and thereby demonstrates that the normal somatic cytolytic defence is still defective. Such an unsatisfactory condition, however, leaves the patient open to the redevelopment of cancer elsewhere should a further gene mutation occur in another group of cells. During the past two years three such cases have been observed. In each there had been clinical evidence of improvement after the removal of the primary local cancer—breast, stomach, and cervix uteri respectively. In each the blood reaction continued positive; in each a further primary cancer ultimately developed; and in each it happened to be of the colon and sigmoid.

The modified Bendien reaction has been shown in other publications to depend upon certain serum biochemical alterations which are also associated with deficiency of normal enzymic content of the blood serum, and that this is accompanied by a deficiency of that cytolytic defence which presumably under normal conditions destroys, by a process of cytolysis, the abnormal type of cell that results from the particular gene mutation producing dedifferentiation; and, experimentally, it has been shown that the recovery of a normal and negative reaction has been associated with re-establishment of a normal blood serum enzyme content and evidence of immunity from recurrence of cancer. Any therapeutic treatment which is followed consistently by such a result would appear worth while pursuing, and the results to which Dr. Hernaman-Johnson refers from his particular method of application of x-ray treatment are definitely encouraging. Somewhat similar results are being obtained by various forms of injection treatment which are being employed in my own clinics, but they must be observed over a longer period of time before evidence can be gained as to whether both the clinical and the serological improvement are maintained.

The observations emphasize what is, I think, a growing consensus of opinion—namely, that the effective prevention and control of cancer recurrence necessitates that, as soon as the requisite local surgical or radiological treatment has been carried out, every case of cancer should be considered an urgent medical problem, and that the state of constitutional deficiency which precedes the clinical development of cancer and usually continues after its surgical removal should be rectified and maintained normal by whatever therapeutic means shows this to be possible.—I am, etc.,

Liverpool, Sept. 20th.

E. CRONIN LOWE.

Treatment of *B. coli* Infections

SIR,—In Professor D. M. Lyon's excellent review of present views on the aetiology and treatment of *B. coli* infections, in the *British Medical Journal* of September 8th (p. 455), there is a strange omission of any reference to the intravesical method of the treatment of urinary infections with this organism. Far be it from me to suggest that the intravesical route is the most satisfactory for the treatment of such cases; my personal experience is too limited to make any such claim. But

as I showed in a paper published in the *Journal* of June 7th, 1925, the intravesical injection of collargol produced a cure, more or less rapid, in 68 per cent. of the small number of cases I had treated in this way. Moreover, the treatment had yielded successful results in the hands of others, including the late Sir Percy Sargent. Experience as a hospital pathologist has shown me that other lines of treatment, although sometimes surprisingly successful, are by no means always so, and in any case are usually lengthy.

In the circumstances it seems unfortunate that intravesical treatment should receive no mention, and therefore tend to be neglected.—I am, etc.,

London, W.8, Sept. 23rd.

HAROLD H. SANGUINETTI.

Rupture of Extensor Pollicis Tendon

SIR,—I have read with interest, in your issue of September 15th (p. 515), the article by Mr. A. T. Andreasen on bilateral rupture of the tendon of the extensor pollicis longus. Although I have not seen a bilateral case, I saw a unilateral one a few months ago which had some similarities to Mr. Andreasen's case. The history in this case is interesting.

The patient, a female, had a slight accident to her right wrist. A short while after this she discovered that she had lost the use of the terminal phalanx of her thumb. On examination there was found to be loss of power in extending the terminal phalanx. It was decided that resuture of the torn tendon was necessary.

At operation the terminal portion of the tendon of the extensor pollicis longus was exposed, but the proximal portion could not be found, in spite of an extensive incision. It was then decided to perform a tendon transplant. The extensor carpi radialis longus was exposed and cut across at its insertion into the base of the second metacarpal bone. The tendon was then sewn to the distal end of the torn extensor pollicis longus. The wound was sutured and the thumb was placed in a moulded plaster-of-Paris splint in the position of extreme extension. The functional result is perfect, and there is no weakness in the movements of the wrist or thumb.

Mr. Andreasen's case is of interest in that he used a slit in the tendon of the extensor of the index finger for anchoring the torn tendon. Should another case present itself to me I should not hesitate to follow his procedure.—I am, etc.,

London, W.1, Sept. 21st.

MAURICE LEE.

Alkali Reserve in Asthma

SIR,—Dr. James Adam's letter in the *Journal* of September 15th very pointedly draws attention to the disputed problem of alkalosis or acidosis in asthma. At repeated intervals one reads the statement that asthma presents an alkalosis, but no evidence of any value is ever brought forward to substantiate this claim. On the other hand, Dr. Adam's own work, and that of others in this country and abroad, does more than suggest the acidotic tendency in this disorder. The reference in Dr. Moll's article to the Tiefensee acidifying diet being beneficial in asthma is largely discounted by the later article of Michel Szour (*Med. Press*, December 9th, 1933, p. 98).

It seems to me that the alkalotic theory, having once been put forward, is accepted without question, and repeated *ad nauseam* without evidence. The same intolerance to all other views is shown by those who are allergic enthusiasts, despite the fact that many, like Dr. Adam, do not accept allergy *per se* as the real cause of asthma, but as an added state within a basic condition. None deny the fact of allergy: they only question its importance. It is obvious that the nose condition described by Adam,

Haseltine, and others is quite misunderstood by their critics. It can be made quite clear that nasal operation is the last thing desirable in asthma, and it is only gross abnormalities which demand it.—I am, etc.,

London, W.1, Sept. 18th. A. J. D. CAMERON, M.B., Ch.B.

The Swab in Diphtheria Diagnosis

SIR,—I have followed this correspondence with interest. In my opinion clinical experience will have to count for much in those patients not children, and probably in a high percentage, owing to the early use in illness of anti-septics such as lozenges, gargles, throat sprays, etc. Fortunately that age group is not the "tracheotomy-danger" one if reliance is placed upon a swab from a disinfected part.—I am, etc.,

Bacup, Sept. 23rd.

J. PERCIVAL BROWN, M.B.

Tuberculin

SIR,—Dr. Halliday Sutherland's letter in the *Journal* of June 30th (p. 1188) has tempted me to relate a personal experience of mine with tuberculin.

Four years ago I worked in a children's hospital near London. Each child admitted to the section in which I was engaged was submitted to an intradermal tuberculin test, O.T. Koch being used. Three dilutions of tuberculin were supplied from a central laboratory. I have no figures, but over one hundred children were tested, their ages varying from about 3 to 12 years.

0.1 c.cm. of 1 in 10,000 dilution was discarded, being too weak.

0.1 c.cm. of 1 in 1,000 dilution was most reliable and safe, as it never caused any general symptoms or local trouble.

0.1 c.cm. of 1 in 100 dilution was never used as an initial test, or if more than a slight flush without induration was caused by the higher dilution. Children negative to 1 in 1,000 dilution, as a rule, gave only slight or no reaction to 1 in 100 dilution, and no general symptoms or local trouble occurred. 0.1 c.cm. of 1 in 100 dilution I consider dangerous as an initial test, and, perhaps, too searching for any test.

Each week, after applying the test to a number of children, I injected, intradermally, into my own forearm, 0.1 c.cm. of 1 in 1,000 dilution. After each injection a well-marked, tender, inflammatory lump developed which persisted for several days. I once injected 0.1 c.cm. of 1 in 100 dilution intradermally. About eight hours later I felt very ill, with severe rigors and temperature 103° F. Next morning my temperature had returned to normal. I felt weak, but did not remain in bed. In forty-eight hours I had recovered completely. There was severe local reaction with blistering, and lymphangitis extending to the axilla. No mistake was made in the dose, because only the three dilutions mentioned were available, and just previously some quite young children had had similar doses. These children, as mentioned, were negative to higher dilutions.

Three members of my family—brother and sisters—died of tuberculosis, and a fourth is an invalid with the same disease. I have been subject to attacks of bronchitis every winter since I was a child. My health has otherwise been quite good, and I am now over 40. My finger nails are slightly curved, but there is no clubbing. For several years past I have examined my purulent sputum every time I got a cough, but have never found any tubercle bacilli. About two years ago I had my chest examined and x-rayed by a leading physician in London. No evidence of pulmonary tuberculosis was found. I had to leave England because of my winter disability.

My single experiment seems to indicate that a severe local and general reaction, following even so small a dose as one thousandth of a cubic centimetre of Koch's old tuberculin, is not proof of active tuberculosis in an adult. It proves also that, to some of us, tuberculin is highly toxic.—I am, etc.,

August 13th.

M.B., D.P.H.

Haemorrhage from Peritonsillar Abscess

SIR,—If Mr. Thomas A. Clarke turns to page 257 of Mr. Irwin Moore's authoritative work *The Tonsils and Adenoids and Their Diseases* (Heinemann, 1928) he will find the following passage:

"Cunningham states that . . . (d) the descending palatine branch of the internal carotid anastomoses with the ascending palatine and tonsillar branches of the external maxillary, and with the ascending pharyngeal."

The gist of Mr. Denis Browne's communication seems to be that haemorrhage following tonsillectomy is venous rather than arterial in origin. Anybody who has seen small arterial twigs spurting in the tonsillar fossa at operation will find it hard to believe this. Again, one often sees a considerable length of the medium-sized vein referred to lying on the capsule of the tonsil after tonsillectomy with the guillotine, and it is remarkable how very seldom haemorrhage follows.—I am, etc.,

Dublin, Sept. 18th.

T. G. WILSON.

Medical Training for Natives in South Africa

SIR,—Our attention has been drawn to a communication from your Pretoria correspondent in connexion with medical and nursing services in the native territories of the Union of South Africa which was published in your issue of July 21st (p. 128). With the proposition that the provision for these services is hopelessly inadequate we are in complete agreement, and we welcome the action of His Majesty's Ministers in the Union of South Africa in deciding to improve the position. Since, however, the remarks of your correspondent may be taken to mean that the medical schools already in existence in this country are unwilling or unable to undertake the work of training natives as doctors, we have thought it desirable to address you on the subject, and to show conclusively that this is not the case.

The position of this university in this matter was set out in Union Government Blue Book 35, 1928, Section 55, which reads:

"55. The resolutions on the subject, which were adopted by the University of the Witwatersrand in October, 1927, are to the following effect:

(a) That, if the Government decides that facilities for the training of non-Europeans in medicine should be provided, the Council considers that no separate school should be instituted for the purpose, but that the facilities should be offered by one of the existing medical schools.

(b) That this University is prepared to undertake the training under the following conditions:

(i) In view of the strong prejudice of the community, non-European students cannot be admitted to the existing medical classes for European students, but they must be taught in separate classes.

(ii) The same training should be given and the same standard demanded as for European students.

(iii) As the finances of this University cannot support the additional burden entailed by the establishment of classes for non-European medical students, full provision should be made for such additional cost, including the necessary buildings and equipment as well as the recurring expenses."

With these resolutions we are still in complete agreement, except that we should not now lay quite so much stress on segregation. Obviously native medical students could not receive their clinical training in European wards, but some of the pre-clinical work could be done in joint buildings. In so far as clinical material is concerned there is an ample supply in Johannesburg. Our one bottle-neck is obstetrics, and even here, with the admirable facilities provided by the Bridgman Memorial Hospital for Natives, we could obtain amply sufficient

cases for the number of native medical students likely to come forward in Johannesburg.—I am, etc.,

University of the Witwatersrand,
Johannesburg, Sept. 4th.

H. R. RAIKES,
Principal.

* Although the views expressed by the Principal are entitled to respect, it must be pointed out that three of the five members of the Government committee, to whose report he appears to take exception, were themselves members of the Board of the Faculty of Medicine of the Witwatersrand University, and therefore presumably well-informed as to the true sentiment of the university. These members were: Sir Edward Thornton, Dr. A. J. Orenstein, and Dr. E. H. Cluver. Further, in spite of public statements as to the willingness of the university to provide higher education for natives (including medical education), no Bantu student has yet been admitted to the university, although there must be numbers of natives desirous of reading medicine, since not a few proceed overseas to British schools to take the course.—ED. B.M.J.

"Port Sanitation and Common Sense"

SIR,—Having spent some years as a port medical officer I was much interested in the article by "Ship Surgeon" in the *Journal* of August 25th, and I should like to express my entire agreement with his very common-sense criticisms.

Bills of health, of which the captain usually produces a bundle, all duly stamped for varying amounts, are seldom looked at, and the present system under which ships from so-called "infected ports" are boarded, crews inspected, and addresses taken regardless of the state of health of those on board, and in the absence of any infectious disease, is an anachronism seldom justified by results. It is immaterial where the ship comes from, provided she is free from infectious disease, and I consider that if the captain or doctor can answer the questions on the declaration of health in the negative, the ship should be given free pratique without reference to the port medical officer. If, however, the captain or doctor is for any reason unable to do so, it is nowadays a simple matter to send a wireless message stating the probable time of arrival, and the port medical officer can then make the necessary arrangements to meet her. I am convinced that if a system on these lines was adopted it would effect considerable economy in time and money without loss of efficiency.

In your editorial of September 8th (p. 480) Dr. White, medical officer for the Port of London, is quoted as expressing the hope that the routine boarding of ships from infected ports may be discontinued. In this I wish him every success, though I fear he will meet with opposition from higher authorities. I have been told many amusing stories of the procedure in some foreign ports—amusing, that is, in retrospect, though undoubtedly irritating at the time—but I think "Ship Surgeon" will agree with me that in English ports he is not pestered for details of the bos'n's lumbago, etc., and that ships are cleared with the least possible delay and inconvenience. At any rate, captains have on several occasions expressed their appreciation of the quick clearance they get in home ports, as contrasted with the delay and irritating inquisition to which they are subjected in many foreign ports.—I am, etc.,

September 20th.

P.M.O.

SIR,—I appreciate the reply by "Ship Surgeon" to my criticism of his original article on "Port Sanitation and Common Sense." I also realize that his remarks were aimed chiefly against the officials in South American and Mediterranean ports rather than against those in Great Britain.

Let me remind "Ship Surgeon" that the questions about cases of illness, etc., are still put verbally by the quarantine officer of H.M. Customs when granting pratique to vessels arriving from ports within the area bounded by the mouth of the Elbe on the east and Brest on the west, for which area the declaration of health does not require completion. His objection to a recital of cases *completely recovered* from illness occurring early in the voyage may at first sight seem reasonable. But what of the fomites? It is essential for the port medical officer to know what has been done in the way of fumigation and disinfection (if anything, has been done at all) to the bedding and the quarters occupied by the patient. In my experience surgeons are apt to be rather vague on this point, and few ships carry the wherewithal to fumigate so important a fomite as, say, the mattress on which the patient lay.

The general practitioner ashore is in precisely the same position as the ship surgeon with regard to "missing" a case of typhoid fever, etc., but experience teaches port medical officers to have typhoid in particular uppermost in mind, as it is the most frequent disease labelled "influenza" or "P.U.O.," especially in the first stages or when of the ambulatory type. I take it "influenza" is one of "Ship Surgeon's" "minor maladies" in the ordinary way. Ninety-nine times out of a hundred "minor ailments" may be mares' nests, but it so happens that the port medical officer has to be constantly on the *qui vive* for the hundredth occasion.

No port medical officer would claim omniscience for an instant, but with great diffidence I would point out that a D.P.H. and/or a D.T.M. and H. are essential qualifications for a port medical officer, in England at least, whereas a ship surgeon requires at present no special qualifications. Until the ship surgeon is legally made the medical officer of health of the vessel he serves in, I feel that the Utopia we all hope for, when much of the routine can be abolished, is still far distant, and the law (ass that it may be) will have to be maintained. I fully appreciate that "Ship Surgeon" was not addressing his remarks at British port sanitary authorities, and I would again like to express the great pleasure it gave me to read his article, a pleasure which I am sure was enjoyed by many others.—I am, etc.,

September 23rd.

A PORT MEDICAL OFFICER.

The Services

Lieut.-Colonel Nanalal Maganlal Mehta, Indian Medical Service, died at Trichinopoly on July 19th, aged 46. He was born on December 31st, 1887, and was educated at the Grant Medical College, Bombay, where he took the L.M.S. in 1910, and at the Middlesex Hospital, taking the M.R.C.S., L.R.C.P. in 1911. Entering the I.M.S. as lieutenant on July 26th, 1913, he became lieutenant-colonel after twenty years' service. He served in the war of 1914-18—in German East Africa in 1914-16 and in the Egyptian Expeditionary Force in 1916-18. After the war he entered civil employ in the Madras Presidency, where he had been civil surgeon, successively, of South Kanara, Coonoor, and Trichinopoly.

Lieut.-Colonel Albert Anderson Meaden, D.S.O., R.A.M.C. (ret.), died after a year's illness at Dymchurch, Kent, on August 31st, aged 58. He was born on June 15th, 1876, the son of the late Rev. R. A. Meaden, was educated at Highgate School and at Bart's, where he gained the Lawrence gold medal and scholarship in 1903, and took the M.R.C.S., L.R.C.P. Lond. in 1902. Entering the R.A.M.C. as lieutenant on January 30th, 1904, he became lieutenant-colonel on October 4th, 1926, and retired on June 15th, 1931. He served in the war of 1914-18, was mentioned in dispatches in the *London Gazette* of February 7th, 1915, and January 1st, 1916, received the D.S.O. in 1916, and served in Afghanistan in 1919, again being mentioned in dispatches. He leaves a widow and one daughter.

Obituary

W. H. TRETHOWAN, F.R.C.S.

Orthopaedic Surgeon to Guy's Hospital

The death of Mr. William Henry Trethowan, at a comparatively early age, came as a great shock to all his friends. He had been unwell with acute tonsillitis, but had made a good recovery, and it was hoped that on the return from his holiday he would come back full of vitality. He unfortunately appears to have developed an acute septicaemia, from which he died on September 12th after a short illness in Stockholm.

He was an exceptionally gifted man. From the outset his career was brilliant: he worked his way up with a series of scholarships and entered Guy's Hospital in 1901.

In 1906 he was awarded the gold medal in the M.B., B.S.Lond.; and subsequently held all the junior house appointments at Guy's. In 1912, after obtaining the F.R.C.S., he was appointed the first orthopaedic surgeon to that hospital. During the war he was chosen by Sir Robert Jones as one of the surgeons to help him in the great work at the Military Orthopaedic Hospital, Ducaune Road, Shepherd's Bush. After the war he was elected surgeon to the Royal

National Orthopaedic Hospital and consulting orthopaedic surgeon to Queen Mary's Hospital for Children, Carshalton.

To those who knew him any obituary notice must sound cold and inadequate, for he was a most remarkable man. He was said by his contemporaries not to have shown in his early days any special surgical aptitude, but the fact remains that, whether it was an inherited or an acquired gift, he succeeded in making himself the most masterly technician of his day. He developed certain methods of his own. He always operated under a tourniquet, and was well known for the length of his incisions—in fact, it was always easy to recognize a case that had been operated on by him. Some used to think that his incisions were unnecessarily long; but when one saw him at work, and saw how the parts seemed to fall away under his magical fingers, and how a difficult operation when performed by him appeared so easy, one realized that though the incision may have been long it greatly simplified the operation. Onlookers were often amazed to see him sew up the wound without ligaturing any vessels, and when questioned upon this he always used to say that if you get down to the bone at its most superficial part and stay there you cannot cut anything of importance. His facility with the knife led him to do operations which other people might hesitate to undertake, and there is scarcely any orthopaedic condition for which he has not at one time or another attempted some bold procedure. His boldness was such that it left his audience flabbergasted, but he seemed to have an uncanny gift of knowing exactly how far he could go with safety. This operative skill in the hands of a lesser man would have been a most dangerous one, but Mr. Trethowan was a very strong critic of himself and was the first to admit if any method he advocated did not come up to his expectations.

He had a very great sense of responsibility—responsibility to his hospitals, to his patients, to his students, to his subordinates. He was continually worrying whether he was teaching his dressers sufficiently and whether full use was being made of the beds he had at his disposal. The trouble he was always up against was how he could reconcile this sense of responsibility to his

hospital work with the clamourings of a colossal practice. The tragedy is that he succeeded, and those who were in close touch with him realized he was doing far too much.

Mr. Trethowan could never think in a groove. Any subject he gave his attention to he always illuminated; consequently, though unorthodox, he was a most inspiring teacher. His out-patient clinics were always well attended, not only by Guy's students but by men from all parts of the world. There was never one moment's dullness while listening to him. He could always extract some interest out of an apparently dull case, and even the proceedings by outbursts of an irrepressible sense of humour. We have already mentioned in how many directions he was torn by his sense of responsibilities and how, at the expense of his health, he succeeded in reconciling it, but there was one duty he overlooked, and that was his duty to posterity. It will always remain a matter of deep regret to his friends and colleagues that the call upon his time was so great that he was not able to put in writing the thoughts that passed through his brilliant brain. He was such a great artist in everything he did that had he elected to write a textbook on orthopaedic surgery there is no doubt that it would have been a memorable volume.

C. L.

E. M. L. writes:

The untimely death of William Henry Trethowan must be deplored by all those who worked with or under him. When, during the world war, the appalling mortality of gunshot wounds of the limbs was realized by the Government, and Sir Robert Jones (then Major-General Jones) was entrusted with the formation and direction among others of the Military Orthopaedic Hospital at Shepherd's Bush, he very wisely decided to form a staff of young surgeons who might be expected to be receptive of new ideas and not have much to unlearn. Among those selected was W. H. Trethowan, who joined the staff as a captain R.A.M.C.(T.) and served on it till some time after the cessation of hostilities, when the hospital was continued under other designations. The lessons which he learnt at Shepherd's Bush Trethowan put into practice at Guy's and at the other scenes of his activity. Trethowan was an outspoken critic of others' work: his own work in the operating theatre was bold but sound. His was always an independent mind, and it was never his habit "jurare in verba magistri" without critical inquiry. Nevertheless the teaching of Robert Jones affected him strongly, and he contributed the article on "The Treatment of Simple Fractures" to Jones's *Text-Book of Military Orthopaedic Surgery* in 1920. He also contributed the article on orthopaedic surgery to Choyce's *System of Surgery*. He was a skilled musician, and among his instruments were the organ and the pianoforte.

JOHN A. MILROY, M.A., M.D.

Professor of Biochemistry, Queen's University, Belfast

We regret to record the death, on September 19th, of Professor John A. Milroy, who came to Belfast as lecturer in physiology in 1902. After a distinguished undergraduate career at Edinburgh he graduated M.B., C.M. in 1896, having obtained the degree of M.A. in 1893. He filled the posts of demonstrator in physiology in Leeds and at Owens College, Manchester, and proceeded to the degree of M.D. in 1902. Part of his post-graduate studies had been undertaken on the Continent, and he gained valuable experience in laboratories in Germany, where his enthusiasm was stimulated and his knowledge extended by studies carried out in that country.

Professor Milroy never lost interest in the work of universities all over the world, and he was familiar with

physiological progress in Germany, Austria, and the Netherlands, whose languages he read in the original text. His wide knowledge of the literature was in frequent demand by his co-workers. In this connexion it is pleasant to record his agreeable personality and ease of approach: no one in search of help ever found a man more willing to assist without leaving any sense of inferiority or animosity, but rather arousing a sense of admiration. "Doctor John," as he was familiarly known, never obtruded his own views solely to stimulate a conflict in a discussion, nor did he ever appear other than kindly, if somewhat shy; nevertheless, he expounded his views with a quiet assurance that was more than helpful. Milroy made many valuable scientific contributions to various journals, with which his colleagues in biochemistry and physiology are familiar. He was one of the contributors to the *Encyclopaedia of Medicine*, but is best known to medical students for his book, *Practical Physiological Chemistry*, of which his brother, Professor T. H. Milroy (who holds the Dunville chair of physiology at Queen's University, Belfast), was part author.

Having filled the post of lecturer in physiology at Queen's University for seven years from 1902 Dr. Milroy, as he then was, succeeded to the lectureship in biochemistry, and subsequently, in 1922, was appointed reader in the same subject. The munificent donation of the late Mr. J. C. White to the university was partly devoted to laboratories and to the establishment of the chair in biochemistry, of which Professor Milroy was the first occupant, and which he held at his death. In this position he more than fulfilled the early promise of his undergraduate days, and his loss leaves a vacancy which will be difficult to fill.

During his thirty-two years' connexion with Belfast Professor Milroy endeared himself to his colleagues and successive generations of students. He was unmarried, and resided with his brothers and sisters, with whom deep sympathy is felt in the medical and academic world of Belfast.

CYRIL CHARLES WILLIAM MAGUIRE, M.D., M.R.C.P.

Physician to Out-patients at Queen's Hospital, Birmingham

Dr. Cyril Maguire died at his residence in Harborne Road, Edgbaston, on September 15th, at the age of 37. He returned from his holidays in Scotland at the end of August, and soon afterwards developed a cold, which led to severe complications, and he died of septicaemia after an illness of about twelve days.

He was the only son of Mr. Bernard Maguire of Stirling Road, Edgbaston, and was educated at St. Philip's Grammar School, and at Birmingham University, which he entered as a medical student in 1916 at the age of 19. He had scarcely embarked on his medical career when he volunteered for military service, and joined the Royal Warwickshire Regiment at the end of 1916. In the war he served with distinction, and was awarded the Italian Military Cross for a special act of bravery, and was twice mentioned in dispatches by the Earl of Cavan. He resumed his medical studies in 1919, and after a distinguished career as a student took his medical degree in 1923.

In preparation for the career before him he held a succession of posts in Queen's Hospital, Birmingham, being in turn house-surgeon, house-physician, medical registrar, and pathologist. In 1926 he obtained the post of physician for out-patients at Queen's Hospital, and after a course of study in Paris and Vienna took up his duties at the hospital. He quickly added to his reputation, and was soon a very popular young physician, held

in high esteem by his colleagues and beloved by his patients. The students appreciated his teaching, and attended both his out-patient clinic and his lectures in large numbers. At the same time he developed a big private practice, and was highly thought of by a wide circle of medical practitioners, who relied on his help in their most difficult cases. Dr. Maguire was joint honorary secretary of the Birmingham Branch of the British Medical Association in 1927-30. He leaves a widow and two children.

An old school friend writes: Cyril Maguire was a man of striking personality. He was always so. Even when a schoolboy he stood forth from his fellows. He worked hard and he played hard. He had a spice of joyous mischief, a heritage from his Irish forebears, which endeared him to everyone. On the football field his vigour was more striking than his orthodoxy, but his coltish figure already gave promise of the impressive physique which so dignified his manhood. At an age when normally he should have been pursuing his medical studies he became a subaltern in the Royal Warwickshire Regiment. He served in France, and later on the Austro-Italian front. He was twice mentioned in dispatches, and earned the Italian Military Cross by a deed of gallantry typical of the man. Two days before the battle of the Piave River he volunteered to enter the Austrian front line trenches to take a prisoner for the purposes of interrogation. With three others he succeeded in his mission, running the gauntlet of fire from the enemy and our own troops. On demobilization he returned to us, not as the homing warrior, but as a man who, having done one job, was eager for the next. As a medical student he displayed the same energy and thoroughness, passing his professional examinations in his stride. As a humorous writer he became a stalwart of the *Queen's Medical Magazine*. He was a man who won and kept the friendship of the many who now mourn his loss. A devout Catholic, his faith was reflected in his daily life. We who loved him knew that no success would spoil him, and his young life was rich with promise.

We regret to announce the death of Dr. JOHN HOLLINGWORTH at the home of his son in Cottingham, Yorkshire. When he retired from active work, on grounds of health, after practising in East Hull for more than fifty-five years, Dr. Hollingworth was the oldest medical man in that city, where his father had practised for many years before him. He was born in 1853, and studied for his profession at the Leeds School of Medicine, obtaining the M.R.C.S.Eng. diploma in 1877. During his earlier years of practice he took an active part in politics, serving as chairman of local Conservative organizations and helping to found the Primrose League in Hull. In later life he was prominently associated with the work of local scientific, photographic, and other learned societies, and his services as lecturer were much in demand. At the time of his retirement last November Dr. Hollingworth had been a member of the local Division of the British Medical Association for fifty-six years. A kindly, competent, well-informed North Country doctor of the old school, with a strong sense of public duty, his memory will long be held in affection by a wide circle of friends and former patients.

The death occurred in Edinburgh on September 20th, of Dr. JOHN YOUNG, who had practised for half a century at Earlston, Berwickshire. He was born in 1855 at Lilliesleaf, Roxburghshire, where his father was minister of the United Presbyterian Church. After a medical course at Glasgow University, Dr. Young graduated M.B., C.M. there in 1883. He spent a period as resident house-

surgeon in the Glasgow Eye Infirmary, and then as house-surgeon in Scarborough Hospital; in the latter town he also engaged for a time in general practice. He then settled at Earlstoun, and became one of the best-known practitioners of the Border region. During the coming autumn he was to have received a public testimonial in recognition of the great affection and esteem in which he was held by his patients, and of his fifty years in practice. Unfortunately, he became ill while on holiday, and died after only a few days' illness. Dr. Young was a keen supporter of the British Medical Association, which he joined in 1887, and at one time was chairman of the South-Eastern Counties Division. He was a devotee of motoring in the early days of this form of transport, and was one of the first doctors in Scotland to use a motor car. He is survived by a widow and two married daughters.

Dr. MARION BALFOUR MARSHALL ROCKWELL, for over thirty years a prominent physician at Amherst, Mass., U.S.A., died there on August 15th. She was born in Scotland on April 24th, 1873, the daughter of Thomas R. Marshall. Educated at Edinburgh and in Germany, she travelled in France and Switzerland before starting her medical studies at the school of the Royal Colleges of Physicians and Surgeons, Edinburgh. Two years later the University of Edinburgh was opened to women students, and Marion Marshall studied there, graduating M.B., C.M. in 1899. She then took a post-graduate course in bacteriology and in ear, nose, and throat diseases, and worked at the Royal Infirmary under Dr. Norman Walker (now Sir Norman Walker). In 1901 she went to America and married Dr. Herbert G. Rockwell, whom she had met at Edinburgh while he was taking a post-graduate course there. In 1902 Dr. Marion Rockwell passed the Massachusetts State Board medical examinations, and shortly after this they moved to Amherst. Dr. Herbert Rockwell enlisted in the medical service during the war, and Dr. Marion cared for her own and her husband's practice while he was on service. He died in 1927. She was a practitioner of unusual sympathy, and was noted for the great amount of charitable work she did. She was a widely travelled woman and an interesting speaker. Throughout the years music provided a delightful refreshment from her strenuous life as a physician. But she loved her medical work, and many of her patients were her personal friends. Though she had travelled extensively in Europe, the East, America, and Canada, she loved to revisit Edinburgh, the home of her childhood. She was a sister of the late Dr. George Balfour Marshall of Glasgow. Dr. Marion Rockwell is mourned by a large circle of friends, both in this country and in America. She was for twenty years a member of the British Medical Association.

The following well-known foreign medical men have recently died: Professor OSKAR WELTMANN, head of the medical department of the Kaiser Franz Joseph Hospital, Vienna, aged 49; Professor TOM RINGEL, director of the First Surgical Department of St. George's Hospital, Hamburg, aged 65; Dr. CONSTANTIN KAUFMANN, founder of the Swiss society of industrial diseases and accidents; Professor KOBAYASHI, director of the lepers' hospital at Oshima, Japan; Professor PIO PEDICINI, a prominent syphilologist of Rome, aged 55; Professor LUIGI SIMONETTA of Milan, a prominent hygienist and Senator of Italy, aged 77; Geh. Med. Rat Dr. PAUL KRAUSE, professor of internal medicine and director of the medical clinic at Münster, aged 62; Professor M. HAMELINCK, a Ghent psychiatrist, aged 51; Dr. VALDEMAR MEISEN, a Danish surgeon and medical historian, aged 56, of coronary thrombosis; and Surgeon General Inspector EMILE CALMETTE, who took part in the Tunisian Expedition of 1881, and during the war was Director of the Medical Service of the 19th Army Corps, aged 83.

Medical News

The opening address of the new session at University College Hospital will be given by Sir John Rose Bradford in the library of the Medical School on Monday, October 1st, at 3.15 p.m. The annual dinner will be held on Friday, October 12th, at 7.30 p.m., with Sir John Parsons in the chair.

The new session at Guy's Hospital Medical School will open on Wednesday, October 3rd, at 2.45 p.m., when Lord Nuffield will distribute the prizes and Mr. C. H. Fagge will give the inaugural address.

The opening of the ninety-third session of the School of the Pharmaceutical Society of Great Britain and the presentation of the Hanbury medal, diplomas, and prizes will take place on Wednesday, October 3rd, at 17, Bloomsbury Square, W.C. The inaugural sessional address will be given by Dr. George Barger, F.R.S., professor of chemistry in relation to medicine in the University of Edinburgh.

The 1934-5 session of the West London Medico-Chirurgical Society opens on Friday, October 5th, at 8.30 p.m., when Mr. Howard M. Stratford will deliver his presidential address at West London Hospital, entitled "A General Practitioner Surveys Psychology." On December 7th papers will be read by Mr. Johnston Abraham on "The History of Syphilis," and by Mr. James Kemble on "The Medical Life of Lord Byron." On January 11th, 1935, Mr. Hugh Cairns will read a paper on "Recent Advances in Intracranial Surgery," and on February 1st Mr. V. B. Green-Armytage will open a discussion on an obstetric subject. A discussion on "Jaundice" will be opened by Dr. J. W. McNee on April 5th.

The annual dinner of the West Sussex Clinical Society will be held at the Dolphin Hotel, Chichester, on Wednesday, October 3rd, at 7.30 p.m. Tickets 8s. 6d. each. Ladies and non-medical guests are invited. After dinner, Dr. Habberton Lulham will deliver a lecture on "Human Nature through a Doctor's Eyes."

The final programme has now been issued for the opening of the new session at the Faculty of Medicine of the University of Birmingham. Besides the usual address and the annual dinner of the school, a series of post-graduate lectures will be given at the affiliated hospitals. On October 4th there will be lectures at the Queen's Hospital in the morning and afternoon; and at 5 p.m. Dr. F. Brett Young will distribute the prizes to students and give an address. At 7.45 p.m. a reception by the dean at the Grand Hotel will be followed by dinner in the Grosvenor Room. On October 5th there will be lectures in the morning at the General Hospital, and in the afternoon at the Children's Hospital, Ladywood Road.

Professor Charles Singer will deliver his presidential address before the London Jewish Hospital Medical Society at the London Jewish Hospital, Stepney Green, E., on "Jewish Influence on Western Europe in the Early Middle Ages," on Thursday, October 4th, at 3.30 p.m.

A series of lectures on "The Prevention of Disease," delivered under the joint auspices of the Royal Institute of Public Health and the Institute of Hygiene at 28, Portland Place, W., opened on September 26th, and will be continued on Wednesdays at 3.30 p.m. to December 12th inclusive.

The old students' post-graduate course at the London Hospital Medical College will be held from Wednesday to Saturday, October 17th to 20th inclusive. The Schorstein Memorial Lecture will be delivered by Sir Farquhar Buzzard, Regius Professor of Medicine in the University of Oxford, in the Medical College on October 18th at 4.30 p.m., and the old students' dinner will be held on that day at 7.30 p.m. in the Trocadero Restaurant, when Dr. J. H. Thomas, a former student, will preside.

The British Institute of Philosophy (University Hall, 14, Gordon Square, W.C.) has arranged a course of four lectures on the importance of a philosophy of life for mental health, for the medical profession, on Thursdays at 5 p.m. from November 1st to 22nd. The first lecture, on "The Biology of Social Life," will be delivered by Professor W. Langdon Brown; the second by Dr. William Brown on "Health, Self-determination, and Free Will"; the third, on "Creative Activity and Mental Health," by Dr. Emanuel Miller; and the fourth by Dr. H. Crichton-Miller on "Belief and Adaptation." Applications to attend the course, the fee for which is 12s. 6d., should be made to the director of studies at the Institute.

A course in tropical medicine and hygiene will be held at the Hamburg Institute for Naval and Tropical Diseases from October 8th to December 8th. Further information can be obtained from the Institut für Schiffs- und Tropenkrankheiten, Bernard Nocht Strasse 74, Hamburg.

A course in cardiovascular diseases will be held at the Hôpital Broussais, Paris, from October 8th to 20th, under the direction of Dr. C. Laubry. The fee is 150 francs. Further information can be obtained from Dr. Lemant, Hôpital Broussais, Paris 14e.

Professor Portmann of Bordeaux will give a course in oto-rhino-laryngological surgery in Paris from October 17th to 24th.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that lecture-demonstrations will be given at 11, Chandos Street, W., at 2.30 p.m. on October 2nd and 9th. Courses of instruction include a week-end course on diseases of the heart and lungs at the Royal Chest Hospital, occupying the whole of October 13th and 14th; medicine and surgery, at the Metropolitan General Hospital from October 8th to 20th, 10.30 a.m. to 6.30 p.m.; cardiology, at the National Hospital for Diseases of the Heart, October 8th to 20th, occupying the whole of each day; ophthalmology, at the Royal Westminster Ophthalmic Hospital from October 15th to November 3rd, every afternoon; clinical surgery, at the Royal Albert Dock Hospital, October 20th and 21st; gynaecology, at the Chelsea Hospital for Women from October 22nd to November 3rd. These courses are open only to members and associates of the Fellowship.

The twenty-second annual meeting of the National Association of Insurance Committees will be held at Scarborough on October 4th, 5th, and 6th.

The Anglo-American Continental Medical Society will hold a meeting in Paris at Dr. Jarvis's (81, Boulevard Maiesherbes) on Saturday, October 6th, at 5 p.m. Medical men who are eligible for membership—that is, those who possess British or American qualifications and are licensed in Europe or contiguous territory—are invited to attend. At an informal dinner afterwards a number of London and Paris guests will be present. We are asked to correct a slip in the report in our *Supplement* of August 18th of the society's luncheon party at Bournemouth during the Annual Meeting of the British Medical Association. The honorary secretary is not Dr. Tom Williams (Bordighera), who was deputed to make the arrangements on that occasion, but Dr. H. J. Spon (6, Via Cavour, Ospedaletti, Ligure, Italy).

Features of special interest in the annual exhibition of the Royal Photographic Society, Russell Square, which closes on October 6th, include a photograph of the third quarter of the moon enlarged to 7 feet by 4 feet; aerial views; photographs taken during operations on the brain; and the application of Grenz rays for radiography of small biological specimens. Considerable advances have been made during the last twelve months in the production of sensitive materials suitable for use with cathode-ray and other high-speed oscillographs. The cathode-ray cardiograph for recording heart beats, and various x-ray cinematograph films are demonstrated on Monday, Wednesday, Thursday, and Saturday evenings, and on Saturday afternoons.

The second international Congress of the History of Science will be held at Madrid under the presidency of E. García del Real from October 7th to 14th. Further information can be obtained from the general secretary, Professor Francesca Vera, Calle de Caracas 8, Madrid.

The annual prize distribution and conversazione of the Royal Dental Hospital of London, School of Dental Surgery (University of London), will take place at the hospital in Leicester Square, W.C., on Friday, October 5th, at 8 p.m., when Professor William Wright will preside.

A congress of the Association for Photographic and Cinematographic Documentation in Science will be held at the State Paedagogic Museum, Rue d'Ulm, Paris, from October 8th to 12th. Further information can be obtained from Dr. Claoué, 39, Rue Scheffer, Paris, 16e.

A severe epidemic of poliomyelitis has recently broken out in Denmark.

Professor Bruno Oskar Pribram, director of St. Hildegard's Hospital of Berlin, has been made a corresponding member of the Société Nationale de Chirurgie de Paris; Dr. Ludwig Robert Müller, professor of internal medicine at Erlangen, honorary member of the Neurological Society of Tokyo; and Dr. Ludwig Frankel, professor of obstetrics and gynaecology at Breslau, honorary member of the Italian and Brazilian Societies of Gynaecology and Obstetrics.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to **THE EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.**

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

THE TELEGRAPHIC ADDRESSES are:

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Medisera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Chronic Bone Sinus

"A. B. C." invites suggestions for the treatment of chronic bone sinus, three to four inches in depth, the result of acute osteomyelitis many years ago. Non-healing is due to a narrow neck, and the cavity being in bone now much sclerosed. Is frequent irrigation after curettage best, or can the vaseline pack be employed? If irrigation, what solution, what strength, and how often? The correct treatment of "saucerization" in this case is impracticable. The disease is one of many years' standing and the patient elderly. Are internal medications, such as pot. iodide, manganese, etc., of any help?

Amidol Poisoning

"M. B." (Aden) wishes to know if there is any chemical inactivating or detoxicating agent other than rubber gloves to prevent amidol poisoning through the skin.

After-effects of Continued Doses of Adrenaline

"X. Y. Z." (London) writes in reply to "L. H." (*Journal*, September 15th, p. 538): Some years ago it was my privilege to see a patient—a chronic asthmatic—who to my knowledge had more than 50,000 injections of adrenaline over a period of twenty-five years in order to relieve his asthma. He was an expert chemist, and always made his own solutions, administering the injections himself. On occasion he had as many as ten doses a day. I never found his blood pressure more than 120 systolic, and his death a few years ago at the age of 74 was due to hypostatic pneumonia. Some other points may interest your correspondent. First, that adrenaline should always be given early in the attack, and that small doses are generally enough—I have seldom found more than 5 minims at one time necessary, while Dr. Hurst states that 3 minims is enough. Secondly, the dose may be repeated if need be. Finally, it would appear to be undesirable to administer adrenaline to an inflamed area.

Senile Pruritus

"EX-SUFFERER" writes from South Africa in reply to the inquiry by "Vrach" (July 28th, p. 192): I recommend the following prescription:

R. Hydrarg. ammon. chlor. 0.06 gram
Nivem hazelini (B. W. and Co.) . . . ad. 64.00 grams
Sig.

An amount the size of a split pea to be rubbed on the affected part until dry.

No scratching allowed. Relief comes within a few minutes.

*Income Tax**Employment of Assistant*

"A. B. T." inquires what effect, if any, would result (a) for the coming assessment, and (b) for the return to be made next April, from the employment of an assistant as from October 1st next.

* (a) No result—the assessment for 1934-5 being based on the profits of the previous year. (b) The cost of the assistant would be deductible as an expense from October 1st, and the return for 1935-6 would be affected accordingly—for example, by the deduction for three months if the accounts are made up to December 31st, and by six months if they are made up to March 31st.

New Practice—Cash Basis

"R. E." acquired his deceased partner's share, and thereafter the practice has been treated as a "new" one. Returns have throughout been on the "cash receipt" basis, but the inspector of taxes now claims that either the sums payable to the deceased partner's estate be brought into the calculation or the gross income be reckoned on the basis of bookings.

* The inspector's attitude is correct, because if "R. E." bases his return on the cash received by him the gross income for the first year or so will be shown at less than the true gross earnings. Probably the best course to follow will be to make the return on the basis of adjusted cash receipts—that is, the amount received plus the increase in the value of the book debts over the period.

LETTERS, NOTES, ETC.

Earwig in Ear

Dr. A. M. VALERIE BONHOTE (Tadworth) writes: At 1 a.m. I was rung up to attend a patient with acute earache. As this was an ante-natal case six weeks from her confinement I was rather anxious. On arrival I found her smiling and apologetic, saying that there was now very little pain. About half an hour before she had woken with a sensation of fluttering in her ear, and told her husband she thought she had a moth in it. She rubbed it, and then had one moment of acute pain, sufficient to make her cry out and wake her neighbours. Since then there had been two attacks of momentary, but less severe, pain; apart from that, there was merely a little discomfort. I found the meatus full of wax, and the drum could not be seen; there was a little blood on the posterior meatal wall, which was disquieting. The other ear was normal in appearance. There had been no history of nasopharyngeal catarrh, and the patient had gone to bed three hours previously feeling perfectly well. The temperature

and pulse were both normal. I decided that it would be safe to leave the patient for a few hours, after inserting some glycerin and carbolic acid drops. I saw her first thing in the morning, and she seemed well, and had had quite a good night. I very cautiously syringed the ear, and to my relief an earwig emerged, together with the wax. The appearance of the drum was interesting: the handle of the malleus was injected, and at one point there was a small scab where the vessel had been punctured. This explained the momentary acute pain and the bleeding—the work of the earwig. I imagine the glycerin and carbolic acid killed the earwig.

Pipe Cleaners' in Gynaecology

Dr. D. V. LATHAM (Mwanza, Tanganyika Territory) writes: Some years ago I conceived the idea of using ordinary pipe-cleaners, doubled up and held in forceps, where previously I had used Playfair's probes. I find the pipe-cleaners very useful, because the wire can be bent to any desired shape, they can be sterilized by boiling, and because, as they are not made by a surgical instrument manufacturer, they can be purchased from any tobacconist at twelve a penny. I am tempted to bring this device to your readers' notice because, on a recent visit to some of the more important teaching centres in the British Isles, I was surprised to find that the clumsy Playfair's probe still held sway.

Diagnosis of Glanders

In an *Epitome* abstract of this subject (No. 95, August 4th, 1934) reference was made to the Strauss test, and it was implied that in this test female guinea-pigs are used as experimental animals. The test actually consists of the intraperitoneal injection of suspected material into a male guinea-pig. This is followed, if the test is positive, by a purulent inflammation of the tunica vaginalis.

Diet Cards at Harrogate

A series of simple diet charts, adaptable to most types of diseases met with at the spa, have recently been drawn up by the Medical Society of Harrogate. They comprise the following varieties: low calorie, restricted carbohydrate-high-vitamin, restricted protein, lactovegetarian, and low fat. Printed on cards and used in duplicate, one of them is given to the hotel and the other retained by the patient. A particular point is the simplicity of the diets, which aims at bringing the scheme within the compass of the smaller hotels and boarding houses. The Harrogate Corporation, which provides us with this information, thus intends to remove the reproach levelled against Harrogate that sufficient attention is not paid to the important matter of diet in connexion with the "cure."

Vitamin D Concentrate

Glaxo Laboratories (56, Osnaburgh Street, N.W.1) have produced an illustrated pamphlet, "A Decade of Vitamin D," to commemorate the introduction in August, 1924, of ostelin liquid. Ten years ago ostelin liquid was prepared by extracting the vitamin D fraction from fish-liver oils; later its vitamin D content was derived from crude irradiated ergosterol; since 1932 this vitamin has been in the form of chemically pure calciferol, and its standardization can thus be effected to a degree of precision that was previously unattainable. Copies of the booklet are available to medical practitioners at their request.

Orthopaedic Treatment of Infantile Paralysis

In Dr. Charles Mackay's letter on page 534 of our issue of September 15th, nine lines from the bottom, the word "possible," through an unfortunate printer's error, appeared instead of "impossible." The sentence should have ended, "... this ideal treatment advocated is not impossible of achievement."

Watson and Sons, Ltd., Sunic House, 43, Parker Street, Kingsway, W.C.2, have issued a pamphlet entitled *Short-Wave Therapy*. A good deal of this is devoted to their "novotherm" valve-operated apparatus, while there are also added indications for treatment and a short bibliography.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 49, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 160.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, OCTOBER 6th, 1934

USE OF NARCOTICS IN THE TREATMENT OF NERVOUS AND MENTAL PATIENTS*

BY

LORD HORDER, K.C.V.O., M.D., F.R.C.P.

PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL

When I was asked to open this discussion before the combined Section of Neurology and Psychological Medicine I protested that I was neither a neurologist nor a psychiatrist. It was thought, however, that some observations by a general physician might prove a good jumping-off ground for the experience of those engaged in these two special branches of medicine. I concurred in this, but I will frankly admit that my acceptance of the invitation was influenced quite as much by my desire to pay homage to the doyen of psychological medicine, whose personal request had so honoured me, as by any other consideration. I shall assume the privilege of opener to present the subject from rather a wide outlook, because my own work leads me inevitably to take such a view, and although the essence of the discussion will turn upon the use of drugs, it can scarcely be out of place for the opener to consider exactly where drugs stand in relation to other measures and what are the indications for their use.

Clearly the term "narcotics," as used in this discussion, is generic, and includes measures that allay pain, whether mental or physical, as well as measures that induce sleep. Otherwise we tend to make a convenient distinction between pain killers or narcotics proper, sleep producers or hypnotics, and measures which bring quiet and poise to the nervous system or sedatives. There is considerable overlap between these groups of therapeutic agents. All narcotics help to produce sleep, either indirectly or directly, but all hypnotics do not relieve pain unless used in doses large enough to produce unconsciousness which is more than mere sleep. In this case they are termed anaesthetics, and are, strictly speaking, outside the limits of our discussion. When the chief cause of sleeplessness is pain then even mild doses of narcotics, by allaying it, may induce sleep indirectly rather than directly, and sedatives, by cooling the fevered brain, prepare the patient for sleep which is then more natural than artificial.

Causes of Insomnia

The key to the successful treatment of insomnia, as in every other disease, is a correct diagnosis. We must track down the cause or causes. Psychological causes have been termed "primary," as against pain, fever, etc., which are regarded as "secondary." But sleep is so essentially a function of the whole organism that such a classification is as unsatisfactory as are most classifications in regard to diseases. Anxiety, or mental pain, is not the only

psychical cause of sleeplessness; all the emotions (remorse, fear, love, anger, sorrow, even joy) may give rise to it. These things require psychological treatment rather than, or as well as, drugs. The attitude of the patient's mind towards sleep and sleeplessness is sometimes very important, and especially the fear that want of sleep may cause him permanent injury. The fact that most people sleep more than is necessary, just as they eat more than is necessary, may be made use of in order to reassure the patient who is troubled on this score.

Purely intellectual brain work rarely, if ever, causes insomnia, provided the work be done under reasonably good physical conditions. But excitement—over-stimulation of the mind—frequently does. How, therefore, the patient spends the day, and especially the end of the day, is an important consideration. In some persons excess of bodily fatigue produces insomnia. More frequent causes are the various forms of dyspepsia, and in this category flatulence is a much more common factor than is pain. Here care is needed in the choice of food and the time of the last meal. Some patients sleep better if no food has been taken for at least two hours, and others if they take a little food just before retiring. For the dyspeptics the best hypnotics may well be an alkali, a carminative, or an antispasmodic.

Circulatory and respiratory troubles carry their special indications. Cough is a great disturber of sleep, and has its own list of causes needing consideration. Defects in the nose and other parts of the upper respiratory tract may also call for treatment; so also does pain, whether inflammatory, visceral, or due to direct nerve irritation as in sciatica and other forms of neuritis—or in neuralgia.

Fever, usually associated with toxæmia, demands special attention when present. Doctors and nurses who have not had experience of dealing with typhoid fever patients find themselves at a loss when the relatively unusual case of this disease appears in a severe form. When typhoid was much more rife and much more serious the routine was better understood and better practised. The influenza epidemic of 1918 found many practitioners ill prepared for the treatment of the sleepless pyrexial patient, the cardinal principle of adapting the bed-clothes to the height of the temperature, for example, rather than to the feelings of the patient, being often neglected. Organic brain diseases not infrequently demand hypnotic therapy, and this even when there is a general subsidence of the cerebral functions so that the patient is quiet for hours together. Encephalitis lethargica sometimes deceives us into thinking that the patient does not need sleep, and this may be a serious error.

* Read in opening a discussion in the Section of Neurology, Psychological Medicine, and Mental Diseases at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Insomnia without Mental or Physical Cause

But we may assume that all these so-called secondary causes of insomnia have been passed in review and have been dealt with so far as is possible. We pass on to the "primary" causes of insomnia. Of course the major psychoses form a very important group; those characterized by excitement are not the only ones requiring hypnotic measures: states of depression may need them quite as much. I shall be followed by speakers who have special experience of handling these patients, so I shall not deal specifically with them. But the sleepless patient who is not the victim of any gross morbid mental defect on the one hand, and who does not suffer from structural bodily disease on the other, presents a problem to all who engage in general medicine.

Before we decide to use any hypnotic drug we cannot know too much about the patient, both his body and his soul. Not infrequently he needs no drug at all, but rather a careful rearrangement of his routine and his habits, and perhaps the restoration of confidence in his ability to sleep, which he may have lost. It is necessary to consider first of all certain general measures. The patient may be, as many of us are, sensitive to noise. If he is intelligent it is not perhaps the actual volume of sound during the night which keeps him awake so much as his appreciation of the fact that certain noises are needless and preventable. This sense of the fitness of things is disturbed, and a process of thought is set going on the matter and a feeling of provocation. Some of us are trying to remedy this evil of needless noise, and I am glad to see that this Association has thought well to express sympathy with our efforts. Next to quiet comes fresh air—proper ventilation of the bedroom. But it must be admitted that if fresh air can only be secured at the expense of extra noise, many patients find that they sleep better if they exclude both.

There is great individual difference in the matter of darkness or light, as there is in that of warmth or coolness; in these things the patient is often a law unto himself. So also is he, as already observed, when food is considered. But in the matter of mental relaxation as a preparation for sleep we probably all follow the same rule, that the more complete this is the more certainly will sleep come to us. Two other general considerations deserve mention—posture and the bed the patient lies on: here are materials for experiment in individual cases.

Indications for Salicylic Preparations

When we come to the question of drugs it is always worth while to consider the simpler remedies first. I have referred already to alkalis, and to carminatives. The salicylic preparations, and especially aspirin, are frequently very useful. Ten grains each of bicarbonate of soda and aspirin—powdered, of course, rather than in tablet form—constitute one of the most useful sleep producers for simple cases of restlessness that I know. The addition of the same dose of bromide of sodium or ammonium will often be effective in even more tiresome cases, where it is important to put a mute upon a too active mind. Smaller doses of pyramidon, or phenacetin, or antipyrine, or a mixture of these, find their indication in another series of cases where there are physical discomforts, such as headache, eyestrain, myalgia, or over-fatigue in the bodily, rather than in the mental, sense. As pure sedatives the bromides are far and away our most useful preparations for controlling discharges of central nerve energy, whether paroxysmal and purposeless as in epilepsy or merely excessive and wasteful.

Of alcohol as a narcotic much might be said. To the tectotaller it is an excitant, and therefore quite useless. To the person accustomed to take it in moderation certain forms of it act as a mild and useful sedative.

Opium, Hyoscine, and Chloral

The great indication for opium and its derivatives is pain, in the presence of which sleep becomes impossible. This is especially so in those conditions in which pain tends to show exacerbations during the night. It is generally quite useless to prescribe pure hypnotics when insomnia is the direct result of physical pain. But the addition of a small dose of such a drug as medinal to an opiate sometimes enables us to give less of the latter than would otherwise be needed. Opium has an undoubted function in some forms of mental pain; very small doses serve at times to produce a state of euphoria, which is helpful in the re-education of the patient's mind along the lines of increased confidence. The older physicians prescribed tinct. camph. co. for the hypochondriac, and one of the best remedies I know for that state of *misère* from which patients of a pessimistic type not infrequently suffer over long periods is a grain of pil. saponis co. twice or three times a day. It has the advantage of not revealing the nature of its essential ingredient, a not unimportant point in these days, when most patients read their prescriptions before they leave our consulting rooms.

The good effects of hyoscine in Parkinson's disease and post-encephalitic Parkinsonism are well known; but this drug is worth exploiting also in some allied states, though always in the smallest doses. For controlling excitement and delirium it is rather dangerous, or so I think. I have seen an excited pneumonic patient felled by it as one fells an ox, the quiet so effectually produced becoming quickly the quiet of death. I do not use the drug in delirium associated with acute infections, or with organic visceral disease. In such patients I rely very largely upon the somewhat old-fashioned mixture of bromide with chloral, and I control delirium tremens by the same mixture, being careful to begin its use too early rather than too late.

Chloral has, I think, gone out of fashion undeservedly. Strangely enough, even bromidia, possessing as it does the attraction of being proprietary, and containing a little of that drug so tinged with romance—cannabis indica—is used very much less to-day than formerly. As to cannabis indica, it is unlikely that many specimens are active, and, when they are, their action is so erratic and individual that it seems largely a gamble if the patient is helped rather than hindered in his search for mental rest.

Of the others of the older group of narcotics, paraldehyde, despite its unpleasantness, still retains a good deal of popularity. Few know the hint given many years ago by Bevan Lewis that tinct. quillaiæ is its best adjuvant. The drug is an alcohol, and therefore acts incidentally as a volatile stimulant—one reason, no doubt, why, with all its nauseous qualities, it becomes occasionally the object of a drug habit. I have known a patient consume a pint in the twenty-four hours, and I remember diagnosing the case as I passed up the street and knocked at the door. For the rest, sulphonal, trional, and chloralamide seem to have lost favour, though we shall doubtless hear if this is as much so in asylum practice as it is in general work. This is an age when direct action is popular, and these drugs, to get their best effects, must be given some time before, and not immediately before, their effect is desired.

Intermediate between these older narcotics and the barbituric group are two bromide-urea compounds which deserve mention—bromural and adalin. I find them both useful, and since not a few patients remind me of the danger of what they call "dope," I am able to assure them that certain recent cautions applied to drugs of an entirely different class.

The Place of the Barbiturates

There is no doubt whatever, I think, that the introduction of the newer group of narcotics, termed "the bar-

biturates," has been a great boon to medicine. I refer, of course, to veronal, medinal, luminal, dial, allonal, and nembital. Not that this exhausts the list: the ingenuity of the chemist and the pharmacist sees to it that the list shall be endless. The British patient, just back from the Black Forest or from Lausanne, proudly takes a carton of the latest isomer of veronal out of her pocket or vanity bag and says: "You will not have seen this new drug, doctor." And she is quite frequently correct. It is claimed for the new preparation that it has all the virtues and none of the drawbacks of the old, and so it may be taken with advantage and with impunity. It seems a pity to dash these hopes in the patient's mind, and, to tell truth, we British are too good doctors to yield to the temptation.

The chief reasons that the barbiturates mark an advance in our available narcotics is that the dosage is more exact and the effects more constant. The number of patients possessing intolerance is very small, and I think the ill effects which have been adduced against their use have been exaggerated.

May I now deal with a few general considerations? In the first place we should remember that there is no ideal hypnotic. To get a constantly reliable effect without passing through a preliminary stage of excitement, to get no gastric irritation or cardiac depression, to get rapid assimilation and equally rapid and complete excretion, and, finally, to get no tolerance established—to get all these things in any drug is impossible. But certain of the barbiturates seem to attain more nearly to this ideal than any other narcotics known to us.

It is not the drug but the drug habit that calls for condemnation. Stimulants and sedatives provide a means of relative or entire escape from the troubles of life, and in this respect narcotics do not differ from alcohol, cocaine, tobacco, and tea. Sleep is one of the safest and pleasantest forms of escaping life. Some folk are able to form this habit of escape without drugs; they are quite as vicious as their less fortunate brothers and sisters who need a drug in order to achieve this blessed oblivion.

I suggest that we pay more attention to the state of the patient's mind and nervous system and less attention to the mere provision of sleep. If we can help him to a state of equanimity during the day, sleep will be more easily won during the night. This leads me to refer to the fact that if half the evening dose of a narcotic be given in the morning and the other half at bedtime the effect is frequently much better. Even such a small dose of medinal as 2 to 2½ grains, say, with 5 grains of bromide, given at (say) eleven in the morning and again on retiring, may be more helpful than if the whole dose be given at bedtime. For one thing the patient is not strung up for the moment of doubt and fear that faces him when the night comes, itself a deterrent against sleep. Again, he does not regard the medicine as a dope of which he is afraid or ashamed, or both—more deterrents.

In other matters it is the day that counts. Patients not infrequently resist a tendency to sleep during the day, lest giving way should prejudice their chances of sleep during the night. I think this is an error. Sleep is a habit—protective no doubt—and I have sometimes found patients sleep better at night if they encourage a doze midday.

Finally, let us remember the efficacy of the sleeping draught (in these days I suppose I should say the sleeping tablet) that is not taken, but stands by the bedside "in case." We must not deny the patient this boon; indeed, we may now insist upon it, for the fear of the dope has with many become greater than the fear of sleeplessness, and we must avail ourselves in the patient's interest of this new fear while it lasts.

OVARIAN CONDITIONS AS CAUSES OF PELVIC PAIN*

BY

DANIEL DOUGAL, M.C., M.D., F.C.O.G.

PROFESSOR OF OBSTETRICS AND GYNAECOLOGY IN THE UNIVERSITY OF MANCHESTER

I welcome the opportunity of being one of the openers of a discussion on ovarian conditions as causes of pelvic pain because the subject is of interest to general practitioner and gynaecologist alike, and both will probably agree that so-called ovarian pain is one of the bugbears of medical practice. The word "bugbear" means "something frightful, as a spectre, or anything imaginary which arouses needless fear," and can only be rightly applied to pain that is supposed to, but does not actually, arise in the ovary. The object of our discussion to-day is to decide what conditions of the ovary do produce pain, or, conversely, how much of the so-called "ovarian" pain is really of ovarian origin.

Before attacking the main problem I would like to recall a few facts concerning the anatomy and physiology of the ovary. Although lying within the abdomen the ovary is not covered by peritoneum, but by a layer of cells, often imperfectly preserved, known as the germinal epithelium. This arrangement no doubt facilitates ovulation. T. C. Clare¹ has pointed out that the ovary is also unique in a physiological sense in that it is the only organ in the body normally subject to trauma and consequent reparatory changes. The trauma consists of the surface wound occurring at the time of rupture of the follicle; the reparatory process is the formation of the small scar by which the lesion is repaired. These two factors, together with a third—the periodic increase of tension within the ovary associated with ripening of the follicle and formation of the corpus luteum—have all to be considered in connexion with the subject of ovarian pain. The presence of follicular cysts in an ovary which is not adherent may be regarded as evidence of disordered function due to overactivity of the anterior pituitary, or, as suggested by Clare, increased formation of fibrous tissue (keloid) in the scars of the ruptured follicles, it being well known that there are wide variations in the regenerative capacity of different individuals.

The ovary is attached to the back of the broad ligament by its hilum, and as both uterus and broad ligament have considerable mobility the position of the ovary must be constantly changing.

The ovarian blood supply comes from both ovarian and uterine arteries, and the venous return is through the pampiniform plexus to the uterine and ovarian veins. On the left side the venous return is said to be somewhat hindered by the fact that the ovarian opens into the renal vein and not directly into the vena cava, but it must be remembered that the pampiniform plexus also drains through the uterine into the internal iliac veins.

The nerve supply is from the aortic plexus of the autonomic system, and reaches the ovary by way of the infundibulo-pelvic ligament and hilum. The surface of the ovary appears to be insensitive to mechanical stimuli, but firm pressure produces, as in the case of the testis, a sickening pain. True ovarian pain is splanchnic, and apparently of a low order; reflected superficial pain of ovarian origin only occurs when the parietal peritoneum is irritated by the ovary.

To simplify the discussion I have divided the ovarian conditions which may produce pelvic pain into four groups, under the headings functional, mechanical, inflam-

* Read in opening a discussion in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

matory, and neoplastic, but as they cover such a wide field and the space at my disposal is limited I propose to devote the greater part of this paper to a consideration of the functional group.

Functional Disturbances

In this group we have to consider those cases in which so-called "ovarian" pain is complained of although no definite pathological lesion can be demonstrated in the ovary.

Exactly thirty years ago, at the Annual Meeting of the British Medical Association at Oxford, the problem of so-called "ovarian" pain was discussed, and the discussion was dominated by the wise scepticism of the late Dr. Herman. You may possibly agree that a similar attitude of mind is right and proper to-day when assessing the value of certain new surgical procedures introduced for the relief of this troublesome symptom.

We have first to consider whether pelvic pain can be produced by follicle and corpus luteum formation, or by ovulation. As regards actual ovulation, it is quite possible that a certain amount of peritoneal pain may occur if blood escapes in quantity from the ruptured follicle.

Visceral pain is produced by tension within the organ affected, and it might be expected that the periodic distension which the ovary has to undergo during reproductive life would as regularly produce pain of that type. Nature, however, has saved womanhood from this misfortune by making the ovary practically insensitive to gradually increasing tension, and therefore it can be said that the follicular cycle is painless, or at the most attended with but slight pelvic discomfort in normal individuals. We must remember, however, that although the uterine contractions during menstruation are also practically painless, they are in some women quite otherwise, and produce the well-known "spasmodic" type of dysmenorrhoea. May not the process of follicle ripening behave similarly and produce ovarian dysmenorrhoea? In both uterine and ovarian cases we may (a) deny that the pain exists, as may be the case in certain hysterical subjects, (b) assume that the threshold for pain has been so lowered, as in neurasthenia, that the normal discomfort becomes a severe pain, or (c) attribute the pain to local disease.

In the case of the ovary the two local conditions which are said to produce pain are cirrhosis and sclero-cystic disease, but Herman² would have none of them, and in opening the discussion already referred to said:

"It is stated that cirrhosis is the final stage of sclero-cystic disease, but those who say it have adduced no evidence that this is so. Sclero-cystic disease is often present without pain. I find no criteria by which a sclero-cystic ovary which caused pain can be distinguished from one that did not. I find no criteria by which cirrhosis of the ovary can be distinguished from the natural shrinking due to age which is not painful nor by which a shrunken ovary which caused pain can be distinguished from one that did not."

And he concluded with these words:

"In brief, I know of no morbid change in a freely movable ovary that causes chronic pain. The so-called 'chronic ovarian pain' is either a reflected pain due to neurasthenia or is a manifestation of hysteria. It is not curable either by surgical treatment of the ovaries or by their removal."

Lhermitte and Dupont,³ on the other hand, are convinced that ovarian dysmenorrhoea exists, and give as its criteria premenstrual pain located in one or other side of the abdomen and radiating to the inner side of the corresponding thigh, with distant manifestations such as gastric disturbances and headaches. They have found the ovaries to be sclero-cystic in patients complaining of severe ovarian pain, and have been able to demonstrate

to their satisfaction various changes in the sympathetic nerve fibres similar to those found when a nerve is caught in a cicatrix.

I have given you two extreme views, and as usually happens the truth will probably be found to lie somewhere between them. There can be no doubt that a certain number of cystic ovaries do produce pain, but it is equally certain that a much larger number do not.

My own view with regard to these functional cases is that a woman with a lowered threshold for pain may genuinely complain of ovarian pain, and that this is produced by pressure upon the sympathetic nerve endings as a result of congestion, increased formation of scar tissue, or cyst formation.

Treatment of Functional Disturbances

Treatment in the first instance should aim at raising the tone of the patient's nervous system by ensuring physical, mental, and emotional rest. If there is no improvement after a thorough trial of these measures the pros and cons of surgical treatment may have to be considered. Conservative measures, such as puncture of the cysts or resection of portions of the ovaries, have been uniformly unsuccessful, and need not be further discussed. Removal of the ovaries is much too drastic a procedure, at any rate in younger women, and, in any case, the resulting menopausal disturbances will place a further strain on the already weakened nervous system.

During the last ten years operations upon the sympathetic nervous system have come into prominence in surgical literature, and, as was to be expected, have been employed in the treatment of various functional disturbances of the female genital organs. Excision of the so-called "presacral" nerve has been extensively employed in cases of uterine dysmenorrhoea, as well as for a variety of other conditions, but is not applicable to cases in which the pain is definitely ovarian. Cotte, whose work on presacral sympathectomy is so well known, has tried to cure some of these cases by periarterial sympathectomy of the ovarian artery in the infundibulopelvic ligament, but with indifferent success.

More recently Lhermitte and Dupont⁴ have published two series of cases in which they excised the ovarian nerves in the hilum of the ovary, and they claim good results, not only in the relief of ovarian pain, but also of those remote manifestations of disturbed ovarian function. Their results, however, are somewhat vitiated by the fact that in most cases other surgical procedures, such as removal of the appendix and hysteropexy, were carried out at the same time.

The operation, however, appears to be fairly easy, reasonably safe, and not harmful to ovulation, so it may be worth trying in those cases in which surgical intervention is considered necessary.

I have already referred to the possibility that the uncomplicated cystic ovary may be the result of endocrine disturbance, and if this be so it is quite likely that organotherapy, when it becomes a more exact science, will prove to be the best method of treatment for cases belonging to this group.

Mechanical Disturbances

The commonest mechanical disturbance of the ovary is prolapse, generally beneath a retroverted uterus, and as a result the ovary becomes more sensitive from congestion or pressure. In the normal individual discomfort or slight pain may be experienced on coitus or on defaecation, but in one who is neurasthenic the pain may be constant, severe, and debilitating.

Varicocele of the broad ligament is said to be frequently associated with ovarian prolapse, but its presence is

difficult to diagnose and its clinical importance somewhat doubtful.

A more serious occurrence is torsion of the ovarian pedicle, but this rarely occurs unless a cyst is present in the ovary. Sudden pain is the principal symptom, and this is partly due to increased tension within the ovary and partly to irritation of the parietal peritoneum by the damaged cyst wall.

Inflammatory Disturbances

Inflammation of the ovary is of frequent occurrence, and usually follows a salpingitis, the infection reaching the surface of the ovary and causing it to become adherent to neighbouring structures. The disturbance of function resulting from these adhesions may lead to cyst formation in the ovary. Infection may occasionally come by the blood stream, as in severe streptococcal infections or some of the acute fevers.

The inflamed ovary is an undoubted cause of pelvic pain, but as it is always associated with pelvic peritonitis, and in chronic cases with adhesions, it is the irritation of, or dragging on, the sensitive parietal peritoneum which is mainly responsible.

So-called "chronic ovarian pain" is frequently diagnosed as "ovariitis," but needless to say there is no pathological foundation for this diagnosis unless the ovary is adherent. The same criterion should apply in the case of the small cystic ovary, the significance of which has already been discussed.

Neoplasms

As a general rule ovarian tumours are practically painless unless torsion, degeneration, or infection occurs, which shows that the ovary is not sensitive to gradual distension.

Endometrioma, however, is an exception, and does, in the majority of cases, produce severe pelvic pain. These tumours are almost invariably adherent, and the pain is partly due to stretching of the ovary by effused menstrual blood and partly to dragging on the sensitive parietal peritoneum and nerves in the broad ligaments.

The annual dinner of the British Serbian Units Branch of the British Legion was held in London at the Lysbeth Hall on September 27th. Lieut.-Colonel A. E. Kidd took the chair, and those present numbered 156, including a large party of Yugoslav ex-service men who were in London for the Federation Interalliée des Anciens Combattants. After dinner the healths of King George and the King of Yugoslavia were drunk, and were followed respectively by the National Anthem and the Yugoslav National Hymn. Colonel P. H. Mitchiner then proposed the toast of "The Guests," and Lieut.-Colonel Lioubomir Stephanovitch and Major Fetherston-Godley, chairman of the British Legion, replied. The Mitchiner silver bell and spoon for marksmanship was presented to Mr. Surtees Shill. The toast of "The Branch and its President" was proposed by His Excellency the Yugoslav Minister, and Colonel Kidd replied. All the speakers stressed the point that of the many branches of the British Legion this Serbian Branch was of particular importance owing to its international significance for Europe. The dinner was followed by dancing, during which the kolo, the Serbian national dance, was performed with much spirit by British and Yugoslavs. Among the principal guests besides those mentioned were Sir James Berry, Madame Agathonovitch, Lady Ralph Paget, Sir James and Lady Purves-Stewart, General Mihailovitch, and Colonel Blackham.

OVARIAN CONDITIONS AS CAUSES OF PELVIC PAIN*

BY

A. H. DAVIDSON, M.D., F.R.C.P.I., F.C.O.G.
MASTER, ROTUNDA HOSPITAL, DUBLIN; PROFESSOR OF MIDWIFERY,
ROYAL COLLEGE OF SURGEONS IN IRELAND

This subject is one which bristles with difficulties and gives rise to much difference of opinion among gynaecologists. It is very controversial, and one's attitude towards its many problems is bound to evoke criticism. In perusing the literature of an older generation one is struck by the ready tendency to blame the ovaries for various vague pelvic pains, and to practise their removal as a means of cure. The frequent failure to relieve and the awful aftermath of the surgical menopause in young women caused a swing of the pendulum to present-day conservatism.

I propose to approach the subject from a purely clinical standpoint, and to consider the ovarian conditions which in my opinion do give rise to pain, mentioning in passing a few interesting cases, and then to discuss the best means of treatment.

It is essential, in the first instance, to accept the fact that it is necessary to find physical signs in the ovary or its neighbourhood before blaming it as a cause of pain, and that in the absence of physical signs it is extremely foolish to adopt any but the most conservative treatment. I, for my part, have experienced the post-operative annoyance of the patient whom I have opened only to find a normal pelvis. Neurasthenic women with ovarian pain are many, and it is much better to place them in the safe hands of a physician.

Ovaries which are the seat of chronic infection, cases of chronic salpingo-oöphoritis, and pelvic adhesions are constantly accompanied by pelvic pain. The burial of the ovary and the consequent difficulty of ovulation may help to produce this, but the drag of peritoneal adhesions also plays a part. The treatment lies in clearing up the pelvis, returning the organs to their normal position as well as possible, and removing what is beyond repair. Adhesions are liable to re-form, but one may count on some amelioration of symptoms.

Intermenstrual pain or "Mittelschmerz" may be considered here. I have seen two undoubted examples of this condition. I opened the abdomen and found enlarged, hard, white ovaries with thickened cortex and very few scars. My treatment consisted in shaving off portions of cortex and making criss-cross incisions. It was all I could think of doing at the time. The result, needless to say, was completely disappointing. When presacral nerve avulsion came into fashion I considered its possibilities in such cases, but fortunately realized in time that the presacral nerve has very little to do with innervation of the ovaries. The ovarian nerve supply derived from the aortic plexus comes down in the ovarian plexus and is delivered through the infundibulo-pelvic ligament and hilum. It is possible that division of the ovarian plexus in the infundibulo-pelvic ligament might relieve this condition, and if I met another case I should be inclined to try it; anterior pituitary hormone might also be a help.

Prolapsed and Cystic Ovaries in the Causation of Pelvic Pain

Prolapsed ovaries lying underneath a retroflexed uterus definitely give rise to pain and sometimes cause very severe dyspareunia. Such ovaries are sometimes cystic, and may have formed light adhesions to surrounding

* Read in opening a discussion in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

peritoneum. They are often congested, and during the premenstrual period they ache and become hypersensitive. A somewhat similar tenderness is produced in cases of varicocele, and here we find a definite referred pain, which is most marked half-way along the line joining the umbilicus to the mid-point between the symphysis pubis and anterior superior spine. This varicocele is an analogous condition to that found in the male which produces a testicular ache. It occurs in the pampiniform plexus, and shows itself as a markedly dilated and varicose condition of the ovarian veins running from the broad ligament through the infundibulo-pelvic ligament. I have noticed it a number of times at operations for chronic retroflexion, and I have seen it relieved by the Gilliam operation, which not only lifts up the uterus but also shortens the broad ligament and so relieves the kink. Pain is also produced in prolapsed ovaries not accompanied by retrodisplacement of the uterus, and this is best relieved by an operation designed to replace the ovary in as nearly normal a position as possible. This can be obtained by stitching a suitable point of the infundibulo-pelvic ligament to the side wall of the pelvis near the interior abdominal ring. One authority reports seventy-six such cases with 88 per cent. of cures.

Endometriomatous growths in the ovaries may cause pain, and ovarian dysmenorrhoea is common in such conditions. These growths tend to come on after the age of 30, and should be suspected in women complaining of dysmenorrhoea and lower abdominal pain starting at this age. Interstitial haemorrhage in the ovary will also produce pain. I have noted these conditions at operation for pelvic pain, but they are not common.

I have little faith in the idea that the small cystic ovary occasions pain, and the so-called cirrhotic ovary is not in my opinion a pathological entity. Adhesions in the region of the infundibulo-pelvic ligament involving or catching up the fibres of the ovarian plexus may result in chronic ovarian pain and dysmenorrhoea. Such a condition has been described by Lupan following removal of appendix; a complete cure was obtained in his case by division of the plexus in the infundibulo-pelvic ligament. Peritoneal bands or adhesions to the ovary can produce pain; I had one such case following an appendicectomy when an omental band had caused internal pain in the rectum for a long period. Division of the band gave complete relief. Large tumours of the ovary, whether malignant or benign, do not as a rule give rise to pain unless the pedicle becomes twisted, causing congestion or formation of adhesions.

It is probable that the ovary itself is fairly insensitive, as otherwise the recurrent follicle ripening, with associated increase of tension, would produce pain. We must recognize, however, that at times the ovaries become more sensitive, for example, just before menstruation, or if there is any marked pelvic congestion; also in cases of repeated unsatisfied sexual stimulation there will develop a hypersensitiveness of the ovary. This is evident by the dyspareunia which sometimes develops in such women.

Apart from organic disease of the ovary we, as gynaecologists, are confronted with three conditions which have been, and will continue to be, dubbed ovarian pain: (a) reflected pain, (b) neurasthenic pain, and (c) hysterical pain. Abnormal conditions of the female genitals affect the lower dorsal and upper lumbar segments of the cord. This causes a hyperaesthesia of the cutaneous areas supplied by these segments, and consequently tenderness and pain on pressure over a fairly wide area situated between the umbilicus and the anterior superior spine. A diagnosis of oöphoritis is often made, although the ovary may be completely free from blame.

In neurasthenia we have a condition in which the resistance of the nervous system is decreased, and consequently the threshold for pain is lowered. This may be produced

by anaemia, chronic disease, long-continued suffering, or mental worry. The patient will complain of pain in the region of the ovary where no ovarian pathology exists. Lastly, in cases of hysteria the patient often fixes her attention on her ovaries, though the ovary is absolutely normal.

The lesson to be learnt from these considerations is that we must be extremely careful when a patient comes to us complaining of pain which she has been told is due to her ovaries. If on examination we find definite physical signs of pathology in her genitalia then we can with confidence recommend operative treatment. If we find the uterus and cervix healthy and normal in position, and we are not sure of the condition of the tubes and ovaries with regard to adhesions, possible endometriomata, displacements, etc., then we should explain the position carefully to the patient and advise an examination under an anaesthetic, and at the same time carry out a Rubin's test. This examination should put us in the position of knowing whether it is necessary to open the abdomen or not. It will also be of value from its suggestion effect on the patient.

Finally, if we are certain in our own minds that there is no pathological condition present we must tell the patient so firmly, and assure her that operative treatment will not improve her condition, and that if she has patience and adopts the measures necessary to improve her general health she will gradually get rid of her pain.

TOTAL THYROIDECTOMY IN THE TREATMENT OF PATIENTS WITH CONGESTIVE HEART FAILURE AND ANGINA PECTORIS

BY

O. BRENNER, M.D.BIRM., M.R.C.P.LOND.
PHYSICIAN FOR OUT-PATIENTS AND PHYSICIAN IN CHARGE OF THE
CARDIOGRAPHIC DEPARTMENT, QUEEN'S HOSPITAL,
BIRMINGHAM

AND

HUGH DONOVAN, M.B.BIRM., F.R.C.S.ENG. AND EDIN.
SURGEON FOR OUT-PATIENTS, QUEEN'S HOSPITAL, BIRMINGHAM

With a Note on the Anaesthetic by

B. L. S. MURTAGH, M.B.BIRM., M.R.C.S., L.R.C.P.
ASSISTANT ANAESTHETIST, QUEEN'S HOSPITAL, BIRMINGHAM

Any measure which promises to prolong, in fair comfort, the lives of patients with both the congestive and the anginal forms of heart failure, in whom the efficacy of all other forms of treatment has been exhausted, must command serious attention, as, if the promise is fulfilled, the method will have a wide application. It is for this reason that the papers of Blumgart¹ and Levine,² and their associates, have excited such great interest. They claim that the removal of the whole thyroid gland in patients without thyrotoxicosis, incapacitated by congestive or anginal heart failure, is not only comparatively safe, but that it so greatly improves the patients' condition that many of them again become capable of work. Blumgart³ says that the operation has now been performed with gratifying success in over fifty cases.

Rationale

It is established that ordinarily the heart's output of blood per minute varies directly as the rate of metabolism. The more rapid the metabolism the more oxygen do the

tissues use, and the more oxygen-containing blood does the heart have to send them. In hyperthyroidism the heart's output is increased because the metabolic rate is raised; in myxoedema metabolism is slowed and the cardiac output is diminished. In the late stages of congestive heart failure the heart's output of blood per minute is diminished, in spite of the fact that the metabolic rate is normal or even increased, and no doubt this is largely responsible for the symptoms at this stage.

Blumgart's preliminary researches were concerned, not with the volume of blood expelled by the heart per minute, but with the linear velocity of blood flow, and this was done in the present series because the linear velocity is easy to estimate, while the estimation of the volume output presents great technical difficulties in patients with congestive heart failure. Blumgart found that in health the linear velocity of blood flow through the lungs was proportionate to the metabolic rate. In hyperthyroidism the velocity was increased. In heart failure, even in its early stages, it was diminished. In myxoedema the velocity was as low as in heart failure, but there were no circulatory symptoms. Blumgart therefore argued that heart failure is due to the heart being unable to maintain a sufficient volume and velocity of blood flow for the needs of the tissues. The damaged heart, on ordinary medical treatment, is pumping the greatest volume of blood at the greatest speed of which it is capable, but the needs of the tissues are unsatisfied. The only course left is to reduce the metabolic needs (by thyroidectomy) to a level at which they can be satisfied by the diminished output of which the heart is capable.

Two further arguments support this. First, the most severe heart failure in cases of hyperthyroidism is usually completely relieved by subtotal thyroidectomy. Most observers agree that thyrotoxic heart failure is not due to organic damage to the heart, but partly to the occurrence of auricular fibrillation and partly to the increased metabolism making excessive demands on the heart. Again, patients with myxoedema rarely have circulatory symptoms, but sometimes, when thyroid extract is given, anginal attacks or congestive failure occurs, and the attempt to cure the myxoedema has to be abandoned.

Levine and Blumgart's Observations

If the argument is correct, improvement might be expected in angina pectoris as well as in congestive failure. It is thought that angina is due to the coronary arteries being unable to transmit enough blood for the increased needs of the heart during exercise. Thyroidectomy diminishes the body's oxygen consumption, both at rest and on exertion. The heart's work is thus reduced, and a large blood supply to the heart becomes unnecessary. Levine and Blumgart⁴ therefore tried the effect of partial thyroidectomy in a number of cases. They found that, though the symptoms were temporarily relieved, the metabolic rate soon rose again and the symptoms recurred, presumably owing to the regeneration of the fragments of thyroid tissue left behind. They also found that irradiation by x rays or radium was useless, as doses which do not damage the other tissues have little effect on the normal thyroid. It was evident that nothing short of total thyroidectomy was likely to succeed, and this was done in another series of cases. They have described in detail⁵ the results in twenty-two cases, including cases of rheumatic, arteriosclerotic, hypertensive, syphilitic, and pulmonary heart disease, with congestive failure, angina, or both. All were unable to work, and many were bedridden.

The results in the twenty-one cases in which sufficient time had elapsed since the operation, after varying periods up to six months, were as follows:

(a) There were two operative deaths.

(b) One patient with frequent attacks of cardiac asthma had no more attacks for three weeks after the operation, but then died in his first post-operative attack. Another, with mitral stenosis and auricular fibrillation, was not improved, and died after a subsequent operation for pericardial adhesions. A third, with syphilitic aortic incompetence, angina, and congestive failure, was not improved, and died a few days after discharge.

(c) Two patients with mitral stenosis, auricular fibrillation, and congestive failure (one of them with a complicating chronic nephritis) were not improved.

(d) Three patients with angina and congestive failure were relieved of their angina. The congestive symptoms were improved greatly in one, slightly in another, and not at all in the third. All three were much more comfortable than before the operation.

(e) One patient with only angina was completely relieved.

(f) Ten patients with congestive failure were much improved. Patients previously orthopaedic and bed-ridden were able to lie flat, and to be up and about without distress, and some were able to return to light work.

(g) Signs of slight hypothyroidism often developed, and small doses of thyroid extract had to be given continuously to five patients, and for a short period to two others. The mental slowness and heaviness of myxoedema rarely appeared, and most of the patients said they were mentally quicker than before the operation, no doubt owing to the improved cerebral circulation. Slight signs of tetany appeared for a few days in some cases, but were easily controlled by calcium and vitamin D.

Present Series

Such successful results in patients hopelessly ill indicated that the method was worthy of further trial, and this paper gives the initial results in a small series of six cases. They had all been observed for months or years by one of us in the out-patient department, Queen's Hospital, Birmingham. They were all incapacitated by their cardiac symptoms, which were slowly progressing in spite of treatment, including, in four cases, one or more periods of in-patient treatment. So far as could be forecast, they had not more than a few months or years of increasingly miserable existence before them. Cases in which the cardiac lesions were rapidly progressing—for example, cases of active rheumatic or syphilitic disease—were excluded. None had clinical evidence of hyperthyroidism, though in some, as is common in heart failure, the basal metabolic rate was raised.

Preliminary Investigations.—In order to diminish subjective errors a number of objective measurements were made before operation for comparison with the post-operative findings, and although the changes in the patients' symptoms were often greater than indicated by the measurements, it may be of interest to record the results in the accompanying table. Radiographs of the heart and electrocardiograms were taken. The venous blood pressure was measured by the direct method, since a rise in the venous blood pressure is a fairly early sign of congestive failure, and a fall usually occurs with improvement. The velocity of the circulation through the lungs was measured by the cyanide method of Weiss and Robb.⁶

About 7 minims of a 2 per cent. solution of sodium cyanide is injected into a vein at the elbow; this travels to the heart, through the lungs (which takes most of the time), and out into the systemic arteries. When it reaches the carotid sinus, at the bifurcation of the common carotid artery, it suddenly stimulates a great transient increase in the rate and depth of respiration. The time between the injection and the first deep inspiration is taken with a stop-watch.

The vital capacity of the lungs was measured by means of a spirometer. It is thought that a vital capacity diminished by the encroachment of distended pulmonary capillaries on the air space, or by the congested capillaries making the lung more rigid, is more closely related

Table Showing the Results of Special Examinations Before and After Operation

Case	Time in Relation to Operation	Venous Blood Pressure in cm. Saline	Pulmonary Circulation Time in Seconds	Vital Capacity in c.cm.	Basal Metabolic Rate (per cent.)	X-Ray Findings	Electrocardiogram
I	Before	7.0 to 12.5	12.5 to 19.6	1,700 to 2,300	- 2 to 0	Heart enlarged to left	Left ventricular preponderance. Depressed S-T I and II. Deeply inverted T I
	After	8.0 to 10.0	10.0 to 17.5	2,000 to 2,300	- 8	Increase in enlargement to left and right	
II	Before	9.3	13.2	2,300	+ 4 to + 15	Heart enlarged to left	Left ventricular preponderance. Diphasic T I and II
	After	0.5 to 3.2	18.6 to 19.6	2,300	- 9	Unchanged	Unchanged
III	Before	17.0 to 22.5	25 to 26	2,300	+ 12	General enlargement of heart	Bundle-branch block of the unusual variety
	After	19.0 to 21.0	29 to 30	2,400	- 5	Slight increase in enlargement	Unchanged
IV	Before	6.0 to 15.2	12.2 to 16.4	1,900	+ 16 to + 20	General enlargement of the heart	Left ventricular preponderance. Diphasic T I and II
	After	8.0	16.3 to 18.0	2,100	0 to + 2	Unchanged	Unchanged
V	Before	2.2 to 3.2	21.6	2,300	+ 19 to + 20	Heart normal in size and shape	Intraventricular block
	After	2.5 to 5.0	21.6	2,500	- 7	Slightly enlarged	Diminished voltage of QRS waves and flattened T waves
VI	Before	4.0 to 10.2	10.2 to 15.4	1,400	+ 28 to + 31	Heart enlarged to left	Left ventricular preponderance. Negative T I
	After	6.0	15.6	1,700	+ 21	Unchanged	Unchanged

to the occurrence of cardiac dyspnoea than is any other factor.

These tests have been done repeatedly on all the patients during the time they were being watched in the out-patient department. In addition, photographs were taken so that any subsequent change in their appearance due to myxoedema might be more readily appreciated. Finally, their exercise tolerance was carefully estimated. Five patients walked up and down the ward until compelled to stop by pain or dyspnoea, and the number of times they walked the length of the ward and the time taken to do so were observed. The sixth patient was able to walk slowly on the flat almost indefinitely, and she was made to walk up a flight of stairs until compelled to stop. In each case the test was repeated several times on different days, and the best result taken for comparison with the post-operative findings.

The Anaesthetic.—Local anaesthesia was not used for several reasons. We thought it desirable to minimize mental stress in patients subject to angina pectoris. The added adrenaline is also liable to bring on anginal attacks. It was thought possible that a cervical block might paralyse the phrenics, with disastrous results in patients already dyspnoeic. Finally, orthopnoeic patients, if conscious, would be unable to lie in the "thyroid position." Avertin-gas-oxygen anaesthesia was ultimately decided upon. Avertin ensures quick induction and avoids pulmonary irritation, but it depresses the circulation and respiration and reduces the blood pressure. Gas and oxygen is non-toxic and non-irritant, and it tends to stimulate the circulation and respiration and to raise the blood pressure, thus counteracting the undesirable effects of the avertin. Glucose was given in large quantities for several days before the operation in order to protect the liver (already damaged by chronic venous congestion) against the toxic action of the avertin. Atropine 1/75 grain was given an hour before the operation. The avertin (0.1 gram per kilo of body weight in 2½ per cent. solution) was given with the patient lying on his left side with his head propped up on pillows, and he remained in that position till narcosis was produced. The patients may, however, be moved to the theatre and placed in the thyroid position on the operating table without undue anxiety. The gas and oxygen was given by Magill's mask and the Clausen harness method. An airway was inserted as soon as possible, and a high percentage of oxygen was necessary in order to maintain a good colour.

The operation must be approached with great circumspection, and the procedure must be delayed if anything occurs which might further handicap the patient temporarily.

Berlin's technique⁶ was that essentially followed.

The whole thyroid gland, with the pyramidal lobe and any near-by nodules of aberrant thyroid tissue, was removed. The chief dangers are that the recurrent laryngeal nerves may be cut and that the parathyroids may be removed. The recurrent laryngeal nerve is best sought for after the upper pole has been freed, and while the lateral lobe is being drawn towards the mid-line. It is a comfort to see that the nerve is safely left behind, but if a careful search shows that it is not running through the terminal branches of the inferior thyroid artery it can be accepted that it is safe. The total removal of the parathyroids can be avoided by observing the following:⁷ (a) the parathyroids, unlike aberrant thyroids, are not rounded, but elongated, flattish, and soft; (b) they are usually wrapped in a little fat; and (c) one or more are usually well away from the thyroid, at least 1 cm. from the lower pole of the gland.

The operation, *pace* those who scoff at the dissecting surgeon, is a *dissection*, to be done deliberately. Haste is more dangerous to the patient than a little extra anaesthesia. After the operation the patient should be kept lying flat until consciousness returns, when he is propped up. Cyanosis should be prevented, while the patient is lying flat, by the use of oxygen.

Records of Six Cases

CASE I

History.—Mrs. K. P., aged 49, hypertension, with coronary sclerosis and ? occlusion. Angina pectoris and congestive heart failure. Under observation since February, 1931. Since 1928 stiffness of left hip, and much pain in the back. Since 1929 severe headaches and retrosternal pain, spreading down left arm to the wrist on exertion. In March and September, 1932, and February, 1933, complained of attacks resembling coronary occlusions—severe cramp-like epigastric pain, coming on while at rest, spreading to the chest, not relieved by amyl nitrite, lasting several hours. Since the first of the attacks ankles began to swell, she became very dyspnoeic and orthopnoeic, and, though just able to get about, was unable to do her housework. In spite of treatment, including two periods in hospital, she continued to go downhill. In addition to her cardiac symptoms she was troubled at intervals by severe pain in the back, associated with osteoarthritis of the spine.

Examination.—She was of the hypersthenic, plethoric type. The left hip showed great limitation of movement. She was orthopnoeic. The liver was large and tender. There was slight oedema of the ankles. The apex beat, which was forcible and heaving, was just outside the mid-clavicular line. The aortic second sound was very accentuated. The blood

pressure ranged from 220/130 to 290/160. The electrocardiogram showed left ventricular preponderance, and a depressed S-T interval in Leads I and II.

Operation.—Total thyroidectomy (January 10th, 1934). Thyroid of average size and appearance, and normal histologically. Her condition caused no anxiety during or after the operation, though for three days her blood pressure fell to 126/76. There was slight pyrexia for three days, and a little cough for a further few days.

Progress.—Her condition greatly improved for two months after the operation. Before operation she had to be propped up in bed with a bed-rest and three or four pillows, and could only walk five times the length of the ward in two and a half minutes before having to stop because of pain and dyspnoea. After the operation she dispensed with the bed-rest and used only three pillows, and she walked six times the length of the ward in two minutes without discomfort, and then stopped only because of the jocular comments of the other patients. After returning home, she found she could walk to hospital and up the stairs to the ward without discomfort, though previously she had to stop many times on her way to hospital. Angina occurred only after excessive exertion, such as walking up three flights of stairs to the laboratory immediately after walking to hospital. Her dyspnoea was also much less, and she was able to use only two pillows without a bed-rest. Her oedema has disappeared. During the next three months, however, she had a return of the pain in the back due to arthritis of the dorsal spine, and her activities were much reduced by this. Her dyspnoea is now greater than in the two months after her operation, though less than before the operation, and she has had no angina at all for the last three months. She feels that but for the pain in the back she is better than she has been for years. She has developed slight hypothyroidism, with puffiness of the eyelids and roughening of the skin, but there is no perceptible slowing of the mental processes, and she herself thinks she is brighter and mentally clearer than before.

CASE II

History and Examination.—Mr. H. P., aged 53. Hypertension, ? coronary disease, and angina pectoris. Under observation since August, 1933. Severe anginal pain, stopping him after walking thirty yards slowly on the level. Unable to do even light work. Unimproved by treatment, including a period in hospital, and prophylactic nitroglycerin. Apex beat one inch outside mid-clavicular line. Accentuated aortic second sound. Thickened arteries. Blood pressure 164/106 to 206/118. Electrocardiogram showed left ventricular preponderance, diphasic T I and II.

Operation.—Total thyroidectomy February 19th, 1934. Gland of average size and appearance, and normal histologically. His condition during and after the operation caused no anxiety, but he developed painful red swellings of the joints of the hands after operation, which troubled him for several weeks. (He had been subject to "rheumatism" for years.)

Progress.—Before operation he developed some pain after walking four times the length of the ward, and was forced to stop after walking eight times in three and a half minutes. After operation he walked ten times the length of the ward in four and a half minutes without pain, though he was slightly dyspnoeic. Since leaving hospital he finds he can walk much further on the flat without pain, but he still gets pain on walking uphill. No evidence of hypothyroidism has developed, though he has put on a little weight.

CASE III

History and Examination.—Mrs. G. W., aged 48. Hypertension, ? coronary disease, congestive failure, and angina. Under observation since November, 1932. Since 1929 increasing dyspnoea on exertion. Unable to walk up flight of eleven steps at home without resting for some period angina on exertion. Oedema of ankle since April, 1932, and swollen abdomen (ascites) since October, 1932. The ascites disappeared under treatment with mercurial diuretics in hospital, but the other symptoms became slowly more marked. She was unable to do any housework. Marked cyanosis and orthopnoea (bolster and three pillows). Marked oedema of

legs, and, when first seen, great ascites, recurring slightly from time to time while under observation. Large tender liver. Apex beat in sixth space two and a half inches outside mid-clavicular line, and dullness one inch to the right of the sternum. Loud systolic murmur in tricuspid area. Pulmonary and aortic second sounds much accentuated. Blood pressure 220/138 to 236/142. Electrocardiogram showed bundle-branch block of the unusual type.

Operation.—Total thyroidectomy, March 28th, 1934. Gland of average size and appearance, except that there was a long pyramidal lobe which was traced to the region of the hyoid, where it tore away. Histologically gland showed some fibrosis, and a parathyroid was seen in its substance. Her condition caused no anxiety during or after the operation.

Progress.—Two weeks after operation she dispensed with one of her pillows, and then, after returning home, with another. Before operation she was stopped by pain and dyspnoea after walking four times the length of the ward in two and a half minutes, and at home had to rest while going up a flight of eleven steps. Two weeks after operation she stopped because of slight dyspnoea, without pain, after walking eight times the length of the ward in three and three-quarter minutes, and she walked twice up and down a flight of twenty-seven steps with no discomfort at all. Since returning home she walks to hospital and up the stairs to the ward without discomfort, whereas previously she had to rest several times on her way to hospital. She has not yet begun to do any housework, though she feels well enough to do so. Her cyanosis is less, she has oedema only of the right leg, which has thrombosed varicose veins, and the liver is not tender, though still large. Her blood pressure is 196/120. There is no evidence of hypothyroidism.

CASE IV

History and Examination.—Mrs. G. D., aged 54. Hypertension, coronary disease, angina, and congestive failure. Under observation since September, 1932. Headaches and increasing dyspnoea since 1929. Angina on effort since March, 1933. Occasional attacks of mild cardiac asthma, lasting up to two hours, since April, 1933. For six months before admission unable to do housework because of dyspnoea and pain. Stout, plethoric, and orthopnoeic. Large tender liver. Apex beat in fifth space in mid-axillary line. Dullness one inch to right of sternum. Blood pressure 236/138 to 270/150. Electrocardiogram showed left ventricular preponderance, diphasic T II and III.

Operation and Progress.—Total thyroidectomy April 11th, 1934. Gland of average size and appearance, and histologically normal. Her condition caused no anxiety during or after the operation. Before operation, stopped because of pain and dyspnoea after walking six times length of ward in six minutes. Twelve days after operation she walked fourteen times the length of the ward in five minutes, and then stopped only because her legs were tired, not because of pain or dyspnoea. After resting fifteen minutes she walked twice up and down a flight of twenty-seven steps without distress. Improvement continued after returning home, and she is now doing all her housework except the heavy washing. The only sign of hypothyroidism is slight roughening of the skin.

CASE V

History and Examination.—Mr. W. N., aged 54. ? old coronary occlusion, angina. Under observation since January 11th, 1934. In October, 1933, while at rest, had severe precordial pain radiating down both arms lasting several hours (probably due to coronary occlusion). Since then anginal pain on slight exertion. Unable to do even light work. Emphysematous chest. Thickening of arteries. Heart of normal size. No murmurs. Blood pressure 152/98. Electrocardiogram showed intraventricular block.

Operation and Progress.—Total thyroidectomy April 11th, 1934. Gland of normal size and appearance, and normal histologically. Somewhat collapsed immediately after the operation, but had recovered the same evening, and after this was troubled only by a little cough, apart from local discomfort. Before operation had to stop, because of pain and dyspnoea, after walking six times length of ward in two and a quarter minutes. The pain was not relieved by prophylactic nitroglycerin, and was no better after three weeks in bed. Several attacks of pain while in bed. Only slight improve-

ment after operation, as the patient still got occasional slight attacks while at rest, and was forced by pain to stop after walking ten times length of ward in three and a quarter minutes. Before operation he had to stop at least six times on his way to hospital. Now has to stop only once, but is still incapable of work. No obvious hypothyroidism.

CASE VI

History and Examination.—Mrs. F. R., aged 58. Hypertension, congestive failure, cardiac asthma, and angina pectoris. Under observation since September, 1933. Since February, 1932, attacks of paroxysmal nocturnal dyspnoea, with precordial pain radiating down left arm. At end of attack brings up about half a pint of frothy sputum. Since onset, increasing dyspnoea and oppression in chest on exertion. Unable to do housework for six months before admission. Thin, nervous woman. Apex beat in sixth space one inch outside mid-clavicular line. Accentuated aortic second sound. Marked arteriosclerosis. Blood pressure 208/110 to 246/140. Electrocardiogram showed left ventricular preponderance, inverted T I.

Operation and Progress.—Total thyroidectomy April 21st, 1934. Gland of average size and appearance, except for cyst 1 cm. in diameter in right lower pole. Normal histologically. Her condition caused no anxiety during or after operation. Before operation was forced to stop after walking twice up a flight of twenty-seven stairs in five minutes. After operation walked three times up and down same stairs in four and three-quarter minutes without distress. She was able to get about much better after discharge, but six weeks after operation she suddenly became unconscious, was paralysed down the right side, and died the same day, after readmission to hospital. Post-mortem revealed a greatly enlarged heart, due to hypertrophy of the left ventricle. There was very little coronary atheroma. A large haemorrhage into the left cerebral hemisphere had burst into the lateral ventricle.

Discussion

It is striking that all six of these seriously ill patients stood the operation so well. One was a little collapsed for a few hours, but the others gave no anxiety. So far only two patients show signs of slight hypothyroidism, in spite of the removal of the whole thyroid gland. Blumgart and Levine also found that the signs of hypothyroidism by no means always appeared. Kocher in 1883 said that myxoedema almost always followed total thyroidectomy, but the collective investigation on myxoedema by the Clinical Society of London in 1888⁸ showed that in many cases myxoedema did not occur. The committee concluded that "the apparent immunity in many cases was probably due to the presence and subsequent development of accessory thyroid glands, or to accidentally incomplete removal, or to the insufficiently long observation of the patients after the operation." All the patients in the present series were middle-aged, and it is possible that the thyroid in middle and old age is less active and less essential than in youth. It is striking that one of the patients displaying the obvious physical signs of hypothyroidism does not show the characteristic mental slowness. This is probably due to the improvement in the cerebral circulation relative to the needs of the brain.

Some improvement in the circulatory symptoms occurred in all cases. In Cases II and V it was slight, in Cases I and VI it was moderate, and in Cases III and IV fairly marked. Patient VI died of cerebral haemorrhage six weeks after the operation; it seems improbable that her death was hastened by it. No patient is free from symptoms, but all were capable of more exertion than before operation, and one has already taken up her housework again, after being unable to do it for more than six months. Some improvement occurred in both the congestive and the anginal symptoms, though previously the patients were going steadily downhill in spite of all treatment. It seems fair to attribute the improvement to the operation and not to rest in bed in hospital,

because all the patients were kept in bed for two or more weeks before the operation without improvement, while four had had one or more previous periods in hospital without benefit. Moreover, the patient was kept in bed for only five to twelve days after the operation.

It cannot yet be foretold how long the improvement will last. As the underlying cardiovascular disease is slowly progressive, it can only be a matter of time before the capacity of the heart is again lowered below the demands of the body, lowered though these are by thyroidectomy, so that sooner or later the symptoms will no doubt recur. The patients are being kept under observation, and it is hoped to make a further report on their condition in about twelve months' time.

The cause of the improvement is not yet entirely beyond doubt. It seems very probable that the main factor is the reduced metabolism. Although the heart can drive on no more blood than before, the small volume it can drive on is now sufficient for the diminished needs of the body. This statement needs modification in two particulars. First, if the needs of the body are reduced so much that the heart, instead of being "all out," is able to reduce its work without the tissues suffering, the heart is rested, and recovers some of its lost reserves, so that it becomes able, when necessary, to expel more blood than before the operation. Secondly, in myxoedema the heart is usually enlarged and less efficient than normal, though the inefficiency is masked by the diminished needs of the tissues. There are also characteristic electrocardiographic changes. Both the enlargement and the electrocardiographic changes usually recede under treatment, showing that they are due to the myxoedema, and not independent changes. In three of the present series the heart enlarged, and in two electrocardiographic changes occurred, after the operation (see table). Any impairment of the heart's efficiency due to myxoedematous changes would tend to counteract the benefits of the reduced metabolism.

Levine pointed out that improvement sometimes occurred at a time when there was no change in the metabolic rate, though the basal metabolic rate usually fell, with further improvement later. This was also true of some of the present series. But too much stress should not be placed on basal metabolic rate readings taken shortly after operation. Possibly apprehension may be responsible for unduly high readings at this stage. Levine suggests that some of the improvement, especially in cases with angina, is due not to the diminished work of the heart but to humoral changes, particularly an alteration of the reaction of the heart to adrenaline. This suggestion is based on his previous work,⁹ in which he stated that in patients subject to angina an attack can always be precipitated by an injection of adrenaline. He suggests that in the absence of thyroid secretion this perhaps may not occur. This seems to be purely speculative, and, moreover, other observers do not agree that angina can always be precipitated by a dose of adrenaline, so that there is no need to consider this hypothesis further at present.

Though the diminished need of the tissues for oxygen-containing blood after thyroidectomy is no doubt the chief factor in the improvement, Blumgart's observations on the velocity of the circulation must not be held to prove this. The linear velocity of blood flow depends not only on the output of blood by the heart per minute, but also on the cross-sectional area of the vessels through which the blood flows. If the volume of blood expelled by the heart per minute and the cross-sectional area of the vessels are both halved, the linear velocity of blood flow remains unaltered. In early congestive heart failure the velocity of blood flow through the lungs may be much slowed, though the output of the heart per minute is practically unaltered. This is

because the dilatation of the pulmonary capillaries increases the cross-sectional area of the vessels through which the linear velocity of flow is measured. The linear velocity of blood flow can therefore be taken as an index of the work done by the heart only if it can be shown that the cross-sectional area of the vessels remains unaltered. In the cases under consideration there is no absolute proof of this, though there is indirect evidence pointing in this direction. The vital capacity of the lungs gives an indication of the cross-sectional area of the pulmonary vessels, since if these are dilated the vital capacity is diminished as the air space is encroached upon. In Blumgart's cases, as in our own, the vital capacity was unaltered or slightly increased, showing that the pulmonary vessels were, if anything, less dilated than before. The velocity of circulation through the lungs after the operation is either unaltered or slowed (see table). These two facts together—namely, a lessened linear velocity through narrowed vessels—show that the volume of blood flowing through the lungs per minute is diminished. Since the output of the left ventricle must equal that of the right, this indicates that the heart as a whole is doing less work.

Summary and Conclusions

The whole thyroid gland has been removed in six patients without hyperthyroidism, showing incapacitating congestive heart failure, angina pectoris, or both, in whom all previous treatment had been ineffectual. There were no operative deaths, though one patient with a very high blood pressure died of cerebral haemorrhage six weeks after the operation. All six patients showed slight to fairly marked improvement in their circulatory symptoms after the operation, and were capable of more exertion. One of them, who had done no housework for over six months, is now doing all her housework except the heavy washing. The cases are all too recent for the permanent effects to be judged, but it is hoped to report on their condition again in about twelve months' time. Slight signs of hypothyroidism appeared in two cases only. The rationale of this method of treatment is discussed.

Juliette Harburger (*Thèse de Paris*, 1934, No. 284) states that during the last two years (1932-3) observations at the Hôpital Laennec, Paris, have shown that alcoholic cirrhosis is three times as frequent in women as in men, and that the disease is more fatal in women (0.73 per cent.) than in men (0.09 per cent.). The malignant hypertrophic forms of cirrhosis are those most frequently found in women, as is shown by the fact that out of twenty-three cases thirteen were hypertrophic and ten atrophic. During the same period 1932-3 alcoholic neuritis showed the same frequency, relative proportion, and characters as in the case of alcoholic cirrhosis, there being four female cases to one male. The inversion of the ordinary frequency of alcoholic symptoms in the two sexes appears to be due both to social conditions, such as the employment of women in factories, and the economic crisis, and to anatomo-physiological conditions, the women representing a new and therefore particularly susceptible soil for alcoholic intoxication.

TRAUMATIC RUPTURE OF THE LUNGS WITHOUT SIGNS OF TRAUMA IN THE CHEST WALL

BY

W. E. COOKE, M.D., F.R.C.P., D.P.H.

As the title suggests, we are concerned in this note with traumatic rupture of the healthy lung. Pathological perforations due to tuberculosis, abscess, emphysema, empyema, neoplasm, etc., and pulmonary laceration by fractured ribs, stabs, and projectiles have been excluded in the cases mentioned, either by necropsy or by the circumstances, age, and history rendering the presence of any of the above conditions extremely improbable. From time to time during the past century these cases have been published. The increase in the number of deaths by violence will, no doubt, bring more to notice, and further emphasize the fact that extensive damage to internal organs—rupture of the lungs, liver, kidneys, spleen, bladder, and intestines, and, for example, extensive retro-peritoneal haemorrhage—frequently occurs without any external evidence of trauma. Injury to the abdominal viscera would appear to be due to direct violence to the organs through the flaccid abdominal wall, as in the case of the passing of a cart wheel, or the wheel of any heavy vehicle, over the abdomen, or by blows or falls in which the abdomen is forced on to a projecting ledge.

Rupture of the lungs cannot be so simply explained. Traumatic rupture of the lungs without injury to the chest wall may be of three types, any of which may occur alone, or the lungs may present all types in varying degree.

Pneumothorax Type

The first condition is simple rupture of a few alveoli, leading to pneumothorax without evidence, such as haemoptysis or haemothorax, to suggest extensive damage to the parenchyma. These cases are not very infrequent, but as the vast majority recover completely they are not published.

Giovanni,¹ in 1861, recorded the case of a boy, aged 15, over whose chest the wheel of a carriage passed. He died on the tenth day. At necropsy no fracture of the ribs or sternum could be detected, but air escaped on opening the thorax. Another instance is the following. A healthy young woman, aged 19, slipped from the top of the household step-ladder, and felt something unusual in her right side. On x-ray examination a pneumothorax was found with complete collapse of the right lung. No fracture of the ribs or other injury to the chest wall could be found. She made an uneventful recovery. No evidence of any lung disease could be found at the time, and radiological examinations at intervals during the subsequent eighteen months failed to detect any signs of tuberculosis.

Parenchymal Rupture

In the second type rupture of the lung parenchyma occurs without laceration of the visceral pleura. On section the lungs present numerous haemorrhages, varying in size from a pea to a walnut, or larger. The haemorrhages completely disintegrate the lung tissue, giving the appearance of cavities filled with blood. In addition, there are ecchymoses throughout the lung fields. Neither pneumothorax nor haemothorax is present, but haemoptysis is constant, and may be the only sign.

Moore² published an example. A healthy young man fell off a horse and sprained the left wrist and bruised the left elbow. No bruise of the chest wall and no fracture of the ribs could be found. He had severe haemoptysis and died three days later. The following is another instance. In 1934 a healthy man, aged 42 years, received a blow on the chin and fell to the ground. He died in a few moments from haemorrhage into the fourth ventricle. No marks of violence

630 Oct. 6, 1934]

TRAUMATIC RUPTURE OF LUNGS

were found, but at necropsy the upper lobe of the left lung presented several haemorrhages in its substance, the largest being the size of a walnut.

Combined Type

The third type is a combination of the foregoing conditions much exaggerated. The visceral pleura is torn, there is haemopneumothorax, and there are extensive haemorrhages into the lung substance.

On May 7th, 1934, a girl, aged 15, collided whilst cycling with an on-coming motor-car, and was thrown into the air. She sustained fractures of the right femur, right humerus, and right clavicle. The ribs and sternum were intact. No bruises could be found on the chest, nor was there any effusion of blood into the muscles of the thorax. The ribs, as one expects in a girl of this age, were very resilient. There were two and a half pints of blood in the right pleural cavity, and the right lung was collapsed. There was a laceration, extending deeply into the lung tissue, six inches in length, on the posterior surface of the right lower lobe, and another two inches in length on the internal surface. The right upper lobe presented a tear, three inches in length, on its anterior surface. In front of this laceration a piece of the lung tissue, two square inches in extent, was almost completely severed. Haemorrhages of various sizes, with disruption of the lung tissue, were present, and numerous ecchymoses mottled the lung fields. The left lung presented similar haemorrhages and ecchymoses, but there was no rupture of the pleura.

Smith³ mentions a case of a boy, aged 8 years, who, in 1896, was run over by a heavy cart. There was not the slightest trace of abrasion or bruising of the skin of the chest, nor behind the ribs and sternum, but the upper lobe of the right lung had been cut completely off from the root of the lung, and was floating freely in a pleura full of blood.

Similar cases are recorded by Le Conte,⁴ Wideroe,⁵ Kerr,⁶ MacTaggart,⁷ and Spiers.⁸

Discussion

Injuries of the type described above must occur frequently, but rupture of the lung is comparatively rare. A convincing hypothesis on the physics of traumatic rupture of the lung is difficult to propound, especially when the characteristics of the normal lung are considered. The recorded cases are almost all in young persons. With the exception of the case mentioned above, MacTaggart's case seems to be the oldest—a man, aged 35, fell from a scaffold thirty-five feet high; his lungs were ruptured, but no ribs were fractured. This suggests that resilience of the ribs may be an important factor. But however resilient the ribs it is unthinkable that direct violence without gross damage to them could rupture the tough, spongy, non-resistant lung unless some other factor or factors were present.

It is reasonable to suppose the other factors to be an expanded lung and a glottis closed at the moment of impact. Given these three conditions—resilient ribs, expanded lungs, and a closed glottis—the effect of sudden violence might be likened to the bursting of a blown-up paper bag between the hands. Both lungs are affected, but greater damage might be expected on the side receiving the greater force.

The absence of bruising in some cases of internal injury and in violence to other parts of the body is a constant source of surprise to the legal mind and to juries. The factors governing the production of bruises are not fully understood, and all that can be said is that violence, and extreme violence, is frequently unaccompanied by bruising.

MORBIDITY IN A FAMILY TREE

BY

WALTER P. KENNEDY, B.Sc., Ph.D.,
L.R.C.P. AND S.E.D.(From the Department of Biology, Royal College of Medicine,
Baghdad)

The study of human heredity is a relatively unexplored part of the young science of genetics; and for obvious reasons progress therein must be slow. Thus it is important to record even a single family tree, to afford material for later research. The present case is brought forward for this reason, and also in the hope that it may interest some practitioners in the investigation of the vast amount of similar material to which they have special access.

The bulk of the records were obtained from the matron of a large hospital, who had kept old family diaries, and who could speak personally of many of the members.

Squares indicate males. Circles indicate females. Blacked-in signs indicate cardiovascular cases. Shaded signs indicate tuberculosis. Signs containing cross indicate malignancy. Half shading indicates individuals still alive. Diamonds indicate siblings of indeterminate history, and the number within the diamond the number of such siblings.

Some individuals were known to the investigator, and in some instances the family physician supplied valuable details. The rest of the data were obtained from others of the family, independent confirmation being sought in all cases. The subject studied was the cause of death, although it is admittedly not an ideal one for such investigations, since it is so frequently uncertain, and post-mortem reports are not commonly available. It can, however, yield a certain amount of information, particularly in instances such as this, where many of the records give clear indication of the major morbid factors.

The tree is given graphically in the figure, and the international convention of nomenclature has been adopted. One generation has been arbitrarily named I, and the ancestor and descendant generations are called AI, DI, and so on. The individuals in each generation are numbered consecutively. Siblings of negative or unobtainable history are indicated by diamonds, the number within showing the number of children. The progeny have not been shown when all the offspring yield no

data of any kind. In-comers by marriage are only given when necessary. Cardiovascular cases are indicated by blocked-out signs, tubercle by cross-shading, and malignancy by a cross. All the members are Scottish, except where otherwise stated.

NOTES ON INDIVIDUAL CAUSES OF DEATH.

Case	Cause of Death	Notes
AI1.1 ...	Paralytic stroke	Over 80
AI1.2 ...	Died in childbirth	4-par. Italian
AI1.3 ...	Apoplectic seizure	Aged 71
AI1.4 ...	Malignant disease (abdominal or pelvic)	Over 60. French
AI.1 ...	Series of paralytic strokes	Aged 63
AI.2 ...	Several paralytic strokes	Over 70
AI.4 ...	"Heart disease"	Aged 64
AI.6 ...	Adult tubercle	—
AI.7 ...	Paralytic stroke	Aged 70
AI.8 ...	Sudden death	Aged 65
AI.9 ...	—	Second wife of AI.8. Cousin of the first wife, AI.7
AI.11 and AI.12	—	Died at 82 and 85 respectively
AI.13 ...	Tumour, probably malignant	—
AI.15 ...	—	Twin; died a few days after birth
AI.16 ...	—	Enlargement of the liver
AI.17 ...	Typhus	Between 40 and 50
AI.18 ...	From uterine fibroid	18 years' invalidism; aged 50
AI.19 ...	Pneumonia	Aged 52
I.1 ...	Tubercle	—
I.2 and I.3	"Strokes"	Over 60
I.5... ..	—	60
I.6... ..	—	60
I.7 ...	Cerebral haemorrhage	Just over 60
I.8... ..	Apoplexy	Aged 48
I.9... ..	V.D.H. and Bright's disease	Aged 59
I.11 ...	—	Alive and well; aged 77
I.12 ...	Tubercle	Husband of I.13, who also died of tubercle when adult
I.14 ...	Tubercle and pneumonia	—
I.16 ...	Cardiac failure	Aged 75
I.17 ...	Cerebral haemorrhage	Aged 80
I.18 ...	Malignant disease	Over 60
I.19 ...	Apoplexy	Aged 73
I.20 ...	Sunstroke in India	Between 40 and 50
I.21 ...	—	Aged 16
I.22 ...	Following upon operation	Nature unrecorded
I.23, I.24, and I.25	? Heart failure	No details
I.27 ...	Tubercle	Aged 12
I.28 ...	Cardiac failure	About 70
I.29 ...	—	Aged 71
I.30 ...	Carcinoma of stomach	Aged 74
I.31 ...	Following prostatectomy	Aged 73
I.32 ...	—	Alive and well; aged 87
I.33 ...	Angina pectoris	Over 60
I.34 ...	Angina pectoris and carcinoma of oesophagus	—
DI.1 ...	Tubercle	When a young adult
DI.2 ...	—	V.D.H. following on acute rheumatism; alive, aged 49
DI.3 ...	—	D.A.H.; alive, aged 35
DI.6 ...	Diphtheria	Aged 12
DI.7 ...	—	D.A.H. and pulmonary congestion; alive, aged 55
DI.8 ...	—	Tuberculous glands in neck; alive, aged 37
DI.9 ...	—	Tuberculous glands in neck; meningitis in infancy; alive, aged 23

NOTES ON INDIVIDUAL CAUSES OF DEATH (continued)

Case	Cause of Death	Notes
DI.10 ...	Tubercle	Over 50
DI.11 ...	—	Acute rheumatism (heart?); alive, aged 31
DI.13 ...	—	Tuberculous glands in neck; alive, aged 38
DI.14 ...	Infantile tubercle	—
DI.16 ...	Died soon after birth	—
DI.17 ...	Pneumonia and tubercle	Aged 16
DI.18 ...	—	Tuberculous hip; alive, aged 34
DI.19 ...	Died in early infancy	—

Summary

Summarizing these results, the notes of 108 individuals are recorded, of whom twenty-one are known to have died from cardiovascular disease (this does not include the case of sunstroke), and five cardiovascular patients are alive; five had malignant tumours, one of whom also had angina pectoris; of thirteen tuberculous cases four patients are alive. Sixteen patients are known to have attained the age of over 70 years, and a further twelve to have passed 60.

In the absence of data regarding the members of whom nothing is recorded, an extended analysis of this tree is scarcely justified. At the same time some support seems to be afforded to Weitz's¹ conclusion that hypertension is a hereditary diathesis. He says:

"It appears to me beyond question that a dominant heredity accounts for the majority of the cases. For most of the others a dominant heredity is probable but not certain; there is a small residue of instances in whose production heredity has not been shown to play a part."

It must also be noted that many of the individuals reached an advanced age, and so the expected incidence of cardiovascular degeneration among them would be much increased. But at the same time, if a hereditary tendency to hypertension is indeed present, as would seem to be the case both in the main stock—that is, progeny of AI1.3, and in the subfamily of AI.1 and AI.2—then it would be expected to manifest itself at the weakest point of the constitution when old age advanced nearer to dissolution.

The hereditary aspects of malignant disease and rheumatoid diathesis are now attracting much attention, while the relation of inheritance to tuberculosis has been extensively investigated. For a full discussion of these subjects, and also of the inheritance of cardiovascular defect, reference should be made to Baur, Fischer, and Lenz,² who deal with the whole topic in a wide and inclusive manner.

The expenses incident to this investigation have been met by a grant from the Ella Sachs Plotz Foundation.

K. O. Evensen, writing in the August issue of *Norsk Mag. f. Laegevid.*, reports a case of aortic rupture in a man aged 52 who lived two and a half days after the rupture had taken place. The clinical symptoms were haemopericardium and ascites. The blood pressure was high, the systolic being 170 and the diastolic 80. The urea in the blood serum was 155 mg. per c.cm. Electrocardiographic examination showed negative T waves in the first two leads. Post mortem, a large heart, weighing 1,000 grams, was found. The pericardial sac contained 800 c.cm. of blood. A nearly complete rupture was discovered 2 cm. above the aortic valve. Macroscopically no morbid changes could be seen on the aortic wall, but, microscopically, slight inflammation changes in the media and some arteriosclerotic changes were detected.

Clinical Memoranda

ACUTE RETENTION OF URINE

AN UNUSUAL COINCIDENCE

The occurrence of acute retention of urine in the same individual twice in less than two years from such different causes as carcinoma of the penis and enlarged prostate may be considered sufficient excuse for the publication of the notes of the case.

The patient, a gnarled old labourer who, after years of toil had found a peaceful haven as a lavatory attendant, was 71 years of age when first seen on February 21st, 1932. He sent for me because he was unable to pass a drop of urine. There had been some slight difficulty for a few days previously. On examination the bladder was found to be distended and there was a large fungating mass at the tip of the penis involving the prepuce and the glans, and apparently completely blocking up the meatus urinarius. The patient was very vague as to how long the growth had been present. I admitted him at once to hospital and ordered him a hot bath and 30 minims of tincture of opium. This failed to relieve him, so after a considerable amount of difficulty I managed to find the meatus and passed a gum-elastic catheter. This was left *in situ* and the bladder drained by stages. As there were no enlarged glands to be felt in either groin, and as the patient's general condition was so feeble I decided that a partial amputation of the penis would have to suffice. This I carried out on February 24th. The wound healed remarkably well, but there was still some difficulty with micturition, so the patient was taught to pass a rubber catheter on himself. He left hospital on March 12th. When I saw him again on March 16th the left leg was swollen and tender on account of a deep venous thrombosis. He continued to pass a catheter on himself until March 23rd, when he found that he could pass water naturally. By the end of March he was walking about again, and in the middle of April he returned to work.

For six months after operation I saw him regularly once a month and thenceforward at two-monthly intervals. There was no sign of recurrence, either locally or in the inguinal glands, and the act of micturition gave rise to no difficulty or discomfort. At the regular inspection on July 12th, 1933, everything appeared to be in perfect order. On July 14th he walked into my consulting room evidently in considerable pain, and reported that he had been unable to pass any water for twenty-four hours. His bladder was felt reaching up to the umbilicus. There was no obstruction at the urethral opening and he was soon relieved by the passage of a large silver catheter. He came again next day and reported passing only a few drops of blood. Examination revealed a moderately enlarged prostate, so into hospital he went again. Drainage of the bladder by an indwelling catheter was resorted to and continued for ten days. The catheter was then removed in the hope that natural function might have been restored. It was not, so a further spell of drainage was tried. At last I decided, with considerable reluctance, that the only choice left open was removal of the prostate. This I did by the suprapubic route on August 21st, 1933. The prostate was the size of a tangerine, with a central flap, which, falling across the urethral opening, completely blocked it, but which was quite easily pushed up out of the way by the point of the catheter. There was a rather severe secondary haemorrhage on the sixth day, but otherwise progress was good and the patient was discharged to his home on October 14th with the wound healed and dry. A few days later a small pin-point fistula formed in the wound, and this remained a source of annoyance, though only a few drops of urine escaped each day until December, when it finally dried up. On December 21st I was sent for late at night and found the patient in agony, with the left testicle swollen and excruciatingly tender. Suppuration followed, and finally the testicle sloughed completely.

The final chapter in this tale of woe was that in March of this year a large hernia appeared through the operation

scar. Now, fitted with a belt, he is able to walk three or four miles a day, pass water "like a king"—as he expresses himself—and he is quite keen to return to his subterranean duties. Incidentally, this case illustrates what an extraordinary amount of trouble can be survived on occasion by one who, judged by all ordinary standards, would be considered a thoroughly bad surgical risk.

Bridlington.

C. J. GORDON TAYLOR, M.D., Ch.B.

TREATMENT OF MAXILLARY FRACTURES

Although fractures of the maxilla are relatively rare, with modern conditions and means of transport they are now becoming increasingly common. Many require very little in the way of surgical appliances, but a certain number may present difficulties which are not easily overcome. The following case, and the method of treatment, may be of interest.

A man aged 52 was admitted to hospital, very shocked, and bleeding profusely from a large laceration at the root of the nose. A fracture extended transversely across

the root of the nose, completely detaching the whole of the maxilla. There was downward and backward displacement of the maxilla of about a quarter of an inch, but the maxilla was freely movable.

The treatment was complicated by: (1) the absence of any articulating teeth; (2) oral sepsis (there were several broken-down teeth and roots present in each jaw); (3) the displacement; (4) facial injuries. Factors (1) and (2) made the use of mandibular-maxillary pressure useless, whilst (3) and (4) were incompatible with the use of a winged maxillary dental splint.

The following splint was devised (see figure), which consists of two main parts—an iron strut fixed to a plaster cap, and a strut having a small vulcanite maxillary dental plate attached to its distal end. The two struts are fastened in the required position by screws passing through a slot, thus giving an adjustable proximation.

The advantages of the method are: (1) comfort to patient and ability to have facial dressings performed without moving splint; (2) the patient can still feed in comfort; (3) he can sleep with head in any required position; (4) he can keep his mouth in aseptic condition; (5) the method provides a strong enough splint to attain and retain anatomical reposition of structures, and there is therefore less likelihood of infection.

W. M. GRAVES-MORRIS, L.D.S. R.C.S. Eng.

London, S.E.1.

Reviews

INFLUENZA

The enormous literature of influenza necessitated the division of the monograph published by the Pickett-Thomson Research Laboratory into two parts. Part I was reviewed in this *Journal* on April 21st and its general standard of excellence commented on. We have not had long to wait for the companion volume,¹ which fully maintains the standard set by its predecessor; the medical profession will be grateful to Drs. D. and R. THOMSON for this comprehensive and valuable book of reference.

Part II opens with a chapter on the complications and sequelae of influenza, and since probably no other infectious disease gives rise to so many complications it is not surprising that their consideration should occupy 300 pages. None have been overlooked—in fact, the authors' policy has been to include all the available published evidence, confining critical remarks to their summaries and conclusions, which follow each chapter or section. The effect of influenza on various physiological states such as menstruation, pregnancy, labour, and the puerperium, and its influence on other diseases are discussed in the next three chapters. The suggestion which has been made occasionally that influenza may initiate such conditions as diabetes mellitus, Addison's disease, and pulmonary cancer is dismissed as extremely doubtful and unproven, but stress is laid on the unfavourable effect of concomitant influenza on many diseases, more particularly pulmonary tubercle and surgical conditions.

Chapter XL is devoted to pathology—a comprehensive account—and this brings us to a consideration of epidemiological data. There is still a lot to learn about the epidemiology of this disease, which is responsible for such enormous and serious pandemics. Is there more than one strain of virus? Is the high mortality of the secondary waves of epidemics due to co-operation between the prime cause and a secondary infecter, the two passing together as one aetiological agent? What is the relationship of interpandemic influenza to epidemic influenza, and how often do we err in the diagnosis of the sporadic case? Only a more intimate knowledge of the prime cause of the disease will enable us to answer these questions, and the authors rightly hail as of fundamental importance the recent work at the National Institute for Medical Research in this respect. Following this are chapters on the mode of transmission, and vaccine and serum prophylaxis and therapy. Everyone will agree that direct transference from patient to patient represents the way in which the great majority of infections take place; although this disease may occasionally be spread indirectly by articles used by the patient this can hardly be of great epidemiological importance.

The authors' summing up on vaccine prophylaxis also is not likely to meet with much dissent. They agree with the view recently expressed by Dochez and his colleagues that by the use of vaccines the incidence of influenzal pneumonia can be lessened; whether the use of vaccines made with the prime causal agent will be of any value only future experiment can decide. Convalescent serum in prophylaxis and treatment has not received extensive trial, and the authors suggest that further work should be done along these lines. Finally, we have chapters on prevention and treatment. Prevention can really be summed up in good personal and

environmental hygiene and avoidance of infection. Attention is rightly drawn to the fact that nasal douches and gargles may be harmful through irritation of the mucous membranes; care should be taken in their choice. The authors have a preference for one containing sodium ricinoleate in an oily medium.

The volume closes with an addendum on work published too late to be dealt with in its appropriate section, a list of some 4,500 references and authors, and subject indices. The authors state that they propose to rest for a few years from the labours entailed in the compilation of these monographs; they surely deserve to.

MEDICAL TREATMENT

The seventh volume of the series on medical therapeutics published in connexion with the chair of therapeutics of the Faculty of Medicine of Paris has now appeared.² This volume deals with the treatment of affections of the blood vessels and kidneys, and like the former ones is brought out under the immediate supervision of Professor LOEPER, who himself contributes several chapters. The subject is divided into sections, each separately considered. For instance, the affections of the kidney are discussed under the headings of the kidney and its response to diuretics, treatment of renal lithiasis, haematuria, urinary antiseptics, tuberculosis of the urinary tract, and general chapters on bleeding as a therapeutic measure, the effect of endocrine gland extracts on renal function, and the principles of dietetics in nephritis. The idea is to approach therapeutics from the clinical aspect, explaining the genesis of the symptoms as an indication for treatment, and the physiological use of a medicament in order to decide whether to prescribe it, or exclude it in varying circumstances. There is thus a certain amount of duplication in the sections, but the articles are well written and full of information. For those who can read easy French this volume will be useful as a guide to modern therapeutics. It is more suitable for a library than for the practitioner's consulting room, as the series is to be completed in nine volumes, each costing 45 to 50 francs.

SURGERY FOR THE G.P.

Surgery of a General Practice,³ by ARTHUR E. HERTZLER and VICTOR E. CHESKY, is a development of a book on minor surgery which appeared four years ago, and it endeavours to give the general practitioner the information he requires for dealing with such surgical conditions as may lie within his scope. The first part is devoted to a consideration of wounds and haemorrhage and all infective conditions, and this is followed by a general survey of the whole of surgery, including the special region of the nose and nasopharynx, and gynaecology, but excluding the abdomen. The concluding portion deals with such technical matters as the preparation of materials, the closure of wounds, bandaging, and general therapeutic methods.

The compression of such a range of material into so brief a compass necessarily means very unequal treatment, and we feel that it would undoubtedly have been better to limit the subject-matter to conditions which the general practitioner may actually be called upon to treat. The injection of the trigeminal nerve, for example, can scarcely come within his scope, whilst half a page is scarcely sufficient for a discussion on carcinoma of the tongue.

¹ *Thérapeutique Médicale*. Vol. vii, *Faissant et Reims*. By Maurice Loeper. Paris: Masson et Cie. 1934. (Pp. 249; 26 figures, 50 fr.)

² *Surgery of a General Practice*. By Arthur E. Hertzler, M.D., and Victor E. Chesky, M.D. London: Henry Kimpton. 1934. (Pp. 602; 472 figures. 42s. net.)

¹ *Annals of the Pickett-Thomson Research Laboratory. Influenza*. Part II. Monograph XVI, vol. x, May, 1934. By D. and R. Thomson. London: Baillière, Tindall and Cox. 1934. (Pp. xix + 951. 53 2s.)

When in the latter case we are told that "complete destruction with the cautery under local anaesthesia gives as good results as most radical operations," and when radium is not even mentioned, we can understand that "treatment is discouraging in the extreme."

Like most American publications, the volume is finely produced and magnificently illustrated. The illustrations alone are well worthy of the study of anyone engaged in the practice of surgery, whether as a general practitioner or as a consultant. Many of them illustrate rare conditions and should be of great assistance in their diagnosis, but we have sufficient confidence in general practitioners in this country to be sure that they will never attempt to treat them.

PICTURES OF EYE DISEASES

There have appeared of late quite a number of atlases of drawings of eye diseases and abnormalities as displayed in the fundus by examination with the ophthalmoscope. Now one has been issued which deals with external conditions. Mr. HUMPHREY NEAME has compiled an *Atlas of External Diseases of the Eye*,⁴ and his fifty-one pictures cover a wide variety of disease. Some are of the simplest and most familiar order, such as the picture of the common sty; others are of an exceptional and rare type such as that of a war injury, the result of burns by dichlorethyl sulphide, or mustard gas. There is not unnaturally a great temptation to include pictures of rarities, just because they may, and in this instance we hope sincerely will, never be seen again. But in a little book that is evidently intended for students such inclusions would seem to be a mistake; rather, the space might have been given to the further illustration of more common conditions, such as interstitial keratitis, of which there are only two illustrations, yet the forms of the disease are protean. Facing each figure there is a page of text. There are terse details on synonyms, symptoms, diagnosis, aetiology, pathology, course, prognosis, treatment, and complications. The drawings are excellent, and the reproduction by process blocks is as good as lithis can be. But the somewhat florid complexion of this means of reproduction makes us sigh for the delicate beauty of the old-time lithography.

BACTERIOLOGY

MACKIE and MCCARTNEY'S *Introduction to Practical Bacteriology* is well known to laboratory workers in English-speaking countries. It has passed through four editions in nine years, each edition providing an expansion of contents without, fortunately, adding much to the bulk of the volume. A feature particularly welcome in the latest edition⁵ is the description of the methods Dr. McCartney has developed for substituting stoppered bottles for cotton-wool-plugged test tubes. The advantages claimed for this is that the stock of media does not get so dry when stored for a few days, and the bottles can be more easily packed and transported. Whether or not the new methods will prove as satisfactory as the old can only be decided by experience, but in the meantime pathologists will be glad to have a description of the new canned medium methods. This book has always been a very good one for reference purposes. During the four or five weeks since it was sent to the reviewer it has happened that he has had to look up a number of points of technique. On each occasion he has looked first to

see if the question was dealt with in the new Mackie and McCartney. The subjects have included methods for the isolation of viruses, the diagnosis of climatic bubo, the natural diseases of guinea-pigs, complement-fixation tests in diseases other than syphilis, and the identification of *Salmonella* bacteria, etc. On each of these subjects he has found something fresh and useful in the new edition of this book.

Dr. GOHAR'S *Elementary Bacteriology*⁶ has been written for medical students preparing for their examination in pathology. It will probably be useful for this purpose because the facts are set out in a pithy way without any detail which the student could regard as redundant. Looked at from a more disinterested point of view the book is open to much criticism, for its many mistakes in spelling (some of which are corrected on an errata slip attached to page 136), and for the poor character of the illustrations. The two sections at the end of the volume, on blood diseases and elementary hygiene, are out of place in a textbook on bacteriology.

SCIENCE AND SOCIAL NEEDS

Professor JULIAN HUXLEY'S *Scientific Research and Social Needs*⁷ is published as the first volume of a library of science and culture which is to be issued under the editorship of Professor H. Levy. The purpose of the library is stated to be the presentation of a picture of the world as science is shaping it. Professor Huxley has undertaken a pilgrimage of survey, at the suggestion of the B.B.C., into the activities of British science, and this volume is partly an account of his survey and partly his comments thereon and those of others with whom he has discussed its bearings. In the first half of the book there are chapters dealing with research in relation to food, building, clothing, health, and transport, and each of these chapters contains records of great interest; the rest is devoted to the discussion of the relations between science and social affairs. The general observation is made that while the applications of science to industry are highly developed and financially supported, biological and humanistic research is relatively undeveloped and ill supported. In arriving at this verdict Professor Huxley does not appear to have taken into account the work that is being done in the medical sciences in institutions throughout the country which are not under public authority and which, presumably, should be included in the humanistic class. Throughout the volume he uses the word "science" in a more restricted sense than is generally favoured to-day, when the tendency is to extend the title to all "gathering of evidence," whether this proceeds to judgement or whether judgement is suspended. He has a particular complaint as to the little use which public authority is making of psychological science, but the reason for this is not far to seek: considering the psychological knowledge at present available and agreed, as distinct from opinions and doctrines, it would be difficult to justify the establishment of a specialist psychological service in public institutions independent of medical service.

The book includes discussions with Professor Levy, with Sir T. D. Barlow on "Research and Industry," and with Professor Blackett on "Pure Science." The discussions with Professor Levy turn chiefly on the political aspects of sociology, and the reader is given glimpses of a society regimented and controlled on "scientific principles," in which all national distinctions have disappeared. Those who plan on this scale might

⁴ *Atlas of External Diseases of the Eye*. By Humphrey Neame, F.R.C.S. London: J. and A. Churchill, Ltd. 1934. (Pp. 110; 51 coloured plates. 15s.)

⁵ *An Introduction to Practical Bacteriology. A Guide to Bacteriological Laboratory Work*. By T. J. Mackie, M.D., D.P.H., and J. E. McCartney, M.D., D.Sc. Fourth edition. Edinburgh: E and S. Livingstone, 1934. (Pp. 504. 12s. 6d. net, postage 6d.)

⁶ *Elementary Bacteriology*. By M. A. Gohar, Ph.D., F.R.C.P.E., M.R.C.P. Cairo: F. E. Noury and Sons. 1934. (6s.)

⁷ *Scientific Research and Social Needs*. By Julian Huxley. London: Watts and Co. 1934. (Pp. 287; illustrated. 7s. 6d.)

profitably consult the experience of the profession of medicine, and among the points in that experience specially worthy of attention are the lessons it has learnt regarding the value of the panacea, the confident dogma, and the too hastily welcomed remedy. The idea that society is a proper object for "scientific" treatment is declared by Professor Huxley to be revolutionary. Presumably he has in mind some wholesale treatment, for the beginnings were made long ago. The idea of running and controlling society as a business venture on scientific principles has its fascinations, and no doubt the few in control would enjoy life; but it would be difficult to find to-day a body of scientists of the first rank who would be willing to draw up a scheme of complete reorganization and to guarantee that, under it, the many would enjoy themselves. One "scientific principle" held, at any rate, by medical science is that the time to apply a remedy is when the result is predictable; application without this proviso is called by another name. The rule is cautious, but is it over-cautious?

In his chapter upon science and health Professor Huxley debates many questions of great importance: to several of them he would be among the first to admit that answers cannot be given. With the answer which he gives to one the medical profession is in complete accord—namely, that the best of all weapons against disease is the maintenance of a high standard of general health.

Notes on Books

With the increasing use of the rhesus monkey for experimental purposes the need for a manual on the anatomy of this animal became imperative. Consequently the American Association of Anatomists in 1930 set up a committee to go into the matter, and a book* has now appeared in which eighteen contributors collaborated. The B.N.A. nomenclature is used throughout, the terminology of human anatomy having been chosen rather than that of comparative anatomy. Nearly all the illustrations were drawn especially for this book by a medical artist, Benjamin Kopel.

Two numbers of *Tabulae Biologicae Periodicae*† which have recently appeared contain collected data over a wide range of biological sciences. Two articles are of interest in relation to human physiology: one on the energetics of contraction of skeletal muscle, and another on blood groups. The former article gives collected data showing the heat production, lactic acid production, oxygen usage, etc., of skeletal muscle. Most of the figures refer to frog's muscle. The particulars have been assembled from seventy-four papers, most of which were published during the last five years. The article on blood groups contains a large amount of interesting data. Diagrams are given which show the relationships between man and the anthropoid apes, as indicated by the blood groups. The inheritance of blood groups is becoming a question of medico-legal importance, and this article shows the chances of inheritance from all the various types of parentage; it also discusses some of the theories of gene distribution that have been advanced to account for these figures. Finally, there are data regarding the geographical distribution of blood groups.

The small monograph *Hallucinations et Délire*‡ written by Dr. HENRY LY, with a preface by Dr. J. Séglas of the Salpêtrière, is based on work carried out in the clinic of Professor Henri Claude. The author discusses the relationship of verbal psychomotor phenomena and hallucinations. He divides hallucinatory phenomena into three main

groups—illusions, hallucinations, and pseudo-hallucinations—which he defines as objectifications of the phenomena of thought and language. In all of these there is both a sensory and a motor component. The book is divided into two sections, the first dealing with hallucinatory symptoms and verbal automatisms, the second with verbal automatisms and delusional forms. It will well repay reading because the author gives the views of the French school of psychiatry, including the well-known work of Clérambault.

Preparations and Appliances

MODIFIED BENEY'S TONSIL CLAMP

Mr. ALEX. TUMARKIN, F.R.C.S.Ed. (Liverpool), writes: Nowadays dissection of tonsils under general anaesthesia is becoming more and more the operation of choice. Haemorrhage is, of course, the main bugbear, and the widespread use of Beney's tonsil clamps is sufficient proof of their efficiency. My own method is to dissect the right tonsil first, and then, as quickly as possible, and without looking for any bleeding points, to apply a large dab to the tonsillar fossa and keep it in place with a Beney clamp. The left

tonsil is treated similarly, by which time removal of the right pack usually reveals a dry fossa. The interval between removing the tonsil and applying the dab should be as short as possible, so as to minimize the brisk haemorrhage which frequently occurs. Unfortunately, using the ordinary Beney handle, one often fumbles for valuable seconds in picking up the clamp, and it is precisely during those seconds that the pharynx can fill dangerously with blood. I have therefore modified the handle simply, so that its points (A A) lie in abduction, as in the figure, instead of adduction. The clamp is thus firmly gripped in the handle and can be picked up and applied in a moment.

The instrument was made to my design by Messrs. Mayer and Phelps of New Cavendish Street, London, W.1.

ACETYLCHOLINE BROMIDE

We have received specimens of acetylcholine bromide prepared in ampoules (0.1 gram in 1 c.cm.) for intramuscular injection (Burroughs Wellcome and Co.).

During the last year it is probable that more physiological research has been carried out in connexion with acetylcholine than in relation to any other single chemical substance. The result of this intensive work has been to show that it is one of the most important chemical regulators of the functions of the body.

The clinical use of this interesting substance is attracting increasing attention. It is dangerous to give the drug intravenously owing to its powerful action on the heart; and, since the blood contains a powerful esterase which breaks down acetylcholine in a few seconds, the substance has little action when given subcutaneously. Intramuscular injections have, however, been found to give satisfactory results. Acetylcholine has been used successfully to counteract post-operative paralysis of the intestine, and to a certain extent to relieve acute constipation. It is also of value in certain types of vascular disturbance associated with arteriolar spasm.

DESITIN OINTMENT

Desitin ointment (prepared by Desitin-Werk, Hamburg, marketed by Messrs. Coates and Cooper, Ltd., 94, Clerkenwell Road, E.C.1) contains cod-liver oil mixed with a basis of soft paraffin, zinc oxide, and talc. The rationale of the preparation is that a local supply of fat-soluble vitamins should promote healing.

NOISE AND HEALTH*

BY

DAN MCKENZIE, M.D., F.R.C.S.Ed.

Can it be shown that noise inflicts definite injury upon body or mind? Is noise harmful, or is it only disagreeable? This inquiry deals with the effect of noise upon the general mind and body, and it leads us into several interesting regions of physiology and psychology. Physically, as we know, noise is a complex of irregular, conflicting, and discordant sound waves—a chaotic jumble. But this physical fact does not interest us much, since we are chiefly concerned not with physical things and vibrations but with living people. So we shall adopt the psychological definition that any sound becomes noise when it is unpleasant. But even this definition needs explaining. What makes a sound pleasant or the reverse?

First of all comes loudness, and we may say that sounds which are painfully loud are harmfully loud, either to ear or to brain, or to both. Here the disagreeable is undoubtedly harmful. Sound may be so loud as to be directly dangerous to life. I have suggested that some of the deaths from high explosives during the war were caused by the shock of sound waves imparting a violent succussion or shaking to the neurones of nerve centres. These, of course, are not the sounds we are ourselves concerned with at present. Our street and traffic noises do not directly endanger life.

Sound in Rhythm

There is, however, no need to dwell upon the particular element of loudness, since it is sufficiently obvious to everyone. But there is another disagreeable quality of noise, of which little or no mention is made, but which deserves notice—namely, that of arrhythmia or unexpectedness. In the matter of rhythm we enter a region of vital mechanics of which we know, even to-day, very little in so far as its fundamentals are concerned. Rhythm, meaning thereby the repetition of an event at regularly recurring intervals, is one of the modes by which time enters into the constitution of the universe as we know it. The question is, of course, the old one: is the element of rhythm imparted to the cosmos by our own mind or is it inherent therein? For the nerve processes themselves function by following a regular rhythm, which seems to vary in different forms of life, although it is fixed for each. In ourselves it seems, moreover, to vary with age, as in childhood it is, like the heart beat, more rapid than in old age, and the more rapid the individual rate the slower do outside events seem to move, as in the time machine of H. G. Wells. Or to put it another way, the more rapid the rhythm the more rapidly does the brain perceive and register impressions. To a child a day is as long and as eventful as a week is to an old man, for the mind measures time, not by the clock, but by its own happenings. That being so, the life of an ephemerid may seem to these insects every bit as long as ours. Their minutes may equal our days. This leads us to a fascinating subject, which, however, I may only glance at—namely, the function of rhythm in the arts, more particularly in those like music and poetry, which appeal to us exclusively or chiefly through our hearing.

Our particular interest in the subject proceeds from the close and intimate connexion that subsists between hearing and muscular movement, in consequence of which, among other effects, we dance and march in time to music. It is, by the way, a remarkable fact that just as there are people who are tone-deaf—that is, people who are devoid of the sense of pitch—so there are people who have no sense of rhythm. Sir Humphry Davy, for example, is said to have been quite unable to keep step in marching. The feeling for rhythm and that for pitch appear to be independent of each other. You may

have no "ear for music" like Sir Walter Scott, and yet be able to dance and to write verse, even verse rhythmically complex such as that in *Hail to the Chief*.

The point to which I wish to direct attention is that rhythmic sound, in which accent or recurring loudness coincides with our movement, as in marching to music, has the effect of preventing or postponing fatigue. For rhythm sustains and carries us onwards as on wings, the sound stimulus passing direct from ear to muscle in such a way as to render our movements automatic. And it is by a free surrender of ourselves to the almost hypnotic influence of musical rhythm that we become such automata. But the automatism, unlike that of true hypnotism, is only partial, seeing that the conscious mind remains fully aware of what is going on. Nevertheless it suffices to release the upper nerve centres from the need of supplying the succession of nerve stimuli necessary to initiate and sustain the muscles in their incessant movement. For continually recurrent acts of volition generated inside the brain there is substituted a periodic stimulus from without. In this way the mind is set free to enjoy the activity of a body that is no longer a burden upon its attention, a drain upon its energy.

From this analysis it would appear that, inasmuch as rhythmic movement in response to music can be continued for surprising lengths of time without leading to fatigue, it is the act of volition, the effort of willing, and not the muscular action itself, that most rapidly tires us. Thus rhythmic or expected sound works along with our natural impulses, and so gives us pleasure. Moreover, it can be made to harmonize with the natural muscular expression, in voice or movement, of our various emotions. We dance and are joyful; we are depressed and solemn as we listen to a funeral march; and in the old days of romantic war, fortresses were stormed to the tune of the "British Grenadiers."

Arrhythmic Sound or Noise

Rhythm pervades creation. But in noise we revert to chaos, a strange, unfriendly world, where every event grates upon our sensibilities. Now whether it is rhythmic or arrhythmic, musical or noisy, sound when it falls upon the ear passes direct to the muscles, exciting them to movement, the rhythmic pleasant, but the arrhythmic unpleasant. Arrhythmic, or as we call it "unexpected," sound startles us, disturbs us, irritates us, apparently because its irregular motion conflicts with the even motion of our being. And as it is a world in opposition, so it necessitates an irregularly recurring adjustment of our mental processes, together with a difficult effort of the will.

The Neuro-muscular Response to Noise

Now in describing the effect of unexpected noise upon the mind I said that "it startles us." Let us examine the phenomenon. Our first reaction to a sudden, sharp, unexpected sound is a muscular start, which places us in a *position of defence*. It is involuntary, and is so rapidly accomplished that our consciousness lags behind the dispositions made, just as it lags behind the events when we are involved in a motor or other accident. I have known a sudden loud bang bring a sleeper out of his bed and on to his feet before he became awake. Along with this "start" there are set in train the changes in the living body which we associate with the emotion of fear: the face pales; the limbs tremble; the male prepares to strike; the female to flee or to faint. In a word, a sudden loud noise arouses fear and all its effects. When sufficiently pronounced it is liable to be followed by what is called "shock," in which there is a general depression of vitality.

I do not for one moment mean to say that every noise we hear and object to startles us and is accompanied by fear and followed by shock. What I do say is that on many occasions a certain degree of those signs and symptoms is induced, and if one is exposed to their continuance a general feeling of fatigue and even exhaustion follows. If, as happens not infrequently, the start having passed, the moment of terror is associated with a moment of paralysis of the will, of hesitation, of oscillation of the

* Abridgement of paper read at the Conference of the Anti-Noise League, Oxford, July 14th, 1934.

body in and out of danger, then you get, for example, the pedestrian's contribution to the accident that may either kill or maim him. In a paper on health and noise this source of ill-health is not to be ignored; nor is the means of prevention to be slurred over. As to that, my own conviction is that the motor hooter should be entirely abolished. It is a deceitful instrument; it confers upon the driver a false belief that he can take risks, and it confers upon the public the false belief that it prevents accidents. I affirm that it causes more accidents than it prevents.

It is because of neuro-muscular disturbance that noise is tiring, and to people who are depressed in health, and particularly to those who are mentally unhealthy or ill-balanced, it may be dangerously tiring. But I know even healthy people who get a genuine migraine whenever they travel in a London tube train. Contrast the muscular reaction from rhythmic sound with that from noise. The one relieves the brain of its burden, lightens its work, and postpones fatigue; the other increases its burden, adds to its work, and so hastens and increases fatigue. There are, of course, great differences in the reactions of people to noise. Some few fortunate persons never seem to suffer any inconvenience at all, and they cannot understand what we are making all the fuss about. At the other extreme we find the hypersensitive; their patron saint is Thomas Carlyle, who once accused a carpenter, working in his house, of breaking the Decalogue with every stroke of his hammer. But between those two extremes there lies the great mass of ordinary men and women who are upset when noise is unusually loud, or when they themselves are out of sorts.

"Accustomed" Noise and its Effect

We must now take notice of a criticism that is frequently levelled against anti-noise work. It is, that as we get accustomed to noise we learn to ignore it, and it then becomes innocuous. This statement is partly true and largely false: true that we learn to ignore it, up to a point; false that it is then innocuous. First of all—and here I appeal to general experience—the everyday noises we can tolerate when we are well and robust become unbearable when we are weary, depressed, or ill. This shows, what the physiologist can understand, that no nerve stimulus or impulse, once initiated, can be annulled.

Nerve energy is as indestructible as any other kind of energy. In noise, whether habitual or occasional, the ear receives and the ear transmits a hyperstimulus to the brain. If we are unaccustomed to it, reaction is manifest in an exclamation or a start—that is to say, in a more or less violent muscular movement—the consequence of the firing of an explosive train. If, however, we are accustomed to it, no reaction is visible, not because the nerve impulse is obliterated, but merely because it is side-tracked and dispersed among a number of subsidiary nerve centres. We are often quite aware of the effort necessary to inhibit or damp down such effects. As the visible reaction is less, so the secondary emotional effects are also reduced, and the phenomenon of fear and shock minimized. But the point is, that although the expenditure of energy is diminished it is not entirely prevented; there is still some waste, and as a result there may be fatigue.

The kind of noise that we most easily get accustomed to is continuous noise. Yet here again the rule of inevitable nerve impulse holds good. The result in this case is, that although the muscular response does not take the form of a start or a jump it nevertheless still manifests itself, this time in continued muscular tension. People whose occupation places them in positions of prolonged strain and responsibility know how restful it is to bring about a state of general muscular relaxation or slackening of fibre. Continuous noise renders such relaxation difficult of accomplishment. And once again you see how it leads to fatigue and even exhaustion.

So we may say that while noise does not induce organic disease, apart from deafness, it does induce a condition of functional weakness or disability, which is manifested in

exhaustion more or less severe according to: (1) the kind of noise; (2) the normal mental and constitutional make-up of the recipient; and (3) the state of his health at the time of his exposure. And this state of fatigue, though not itself disease, opens the door to disease.

Here we have one of those functional upsets that may lead to organic troubles. A healthy man in full vigour can stand ordinary diurnal street and traffic noise without suffering much, if any, damage. Not so, however, the hypersensitive and the weakly. Noise makes them irritable, and irritability is a sign of asthenia. I have heard robust men blame the hypersensitive because they suffer from such excessive nerve stimuli. But the problem is not to be solved by cursing these people. We may not all be hypersensitive, but there are very few of us who have not our hypersensitive moments, when noise, even moderately loud noise, becomes an intolerable irritant.

Noise and the Sick

There remains still to be considered an aspect of the subject which calls for direct and deliberate attention, and that is the deleterious effects of noise upon the sick. There are many diseases, mostly acute, in which quiet is of supreme importance; much more important often than feeding. Yet, while minute dietetic directions may be given by their medical attendants, "quiet" is, as it were, understood. Take pneumonia, the septic infections, those forms of heart disease that are attended with insomnia, post-operative states, the melancholy troubles of nervous sufferers that form the borderland between sanity and insanity—these are only a few of the commoner diseases in which rest and sleep are not only desirable but imperative if the patient is to recover rapidly and smoothly. How do they fare to-day? Go round any of the London nursing homes and hospitals and ask the ward sisters, or become a patient and make the experiment yourself. I am sure if noise could be reduced, so would the consumption of 'sleeping-draughts'.

It is true, no doubt, that much of the noise disturbance in nursing homes and hospitals comes in from the streets; but not all of it. Too much is generated within the hospital itself. Doors are banged, blinds rattle, lift gates crash, tin pails clatter, and a hundred other noises, great and small, are constantly occurring. This ought to be stopped. One of the ideals, too often forgotten, not only in the construction but also in the running of a hospital or nursing home, is the ideal of *quiet*. Apart altogether from the exclusion of an irritant, the positive value of a calm and soothing environment upon the subconsciousness of a sick person is inestimable. It helps to constitute the therapeutic atmosphere, and, by soothing the patient's apprehension, aids in the cure of his disease, as the old Greek physicians of the Aesculapian temples knew. Not only in health, but also in sickness the ideal of quiet is one that we modern physicians have lost. Should we not try to regain it?

R. Benard and G. Thoyer (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, July 2nd, 1934, p. 1069) record a case of Addison's disease to demonstrate the respective actions of suprarenal cortical and medullary extracts in this malady. Primary treatment with the former caused rapid disappearance of the acute symptoms, particularly the asthenia, but had no effect on the blood pressure. Conversely, the medullary extract, which was then given, produced a marked durable rise in the arterial tension without influencing the asthenia, which reappeared in a few days, rapidly disappearing, however, on the resumption of the cortical extract. The patient has remained well and active for three months following the total cessation of treatment. A daily dosage of 1 gram of the cortical extract may be safely administered, provided that this maximum amount be attained by progressive doses and given in two divided daily doses. Bédère suggests that the extract does not act, as in thyroid medication, by supplementing an endocrine insufficiency, but by favouring a compensatory hypertrophy of the portions of the suprarenal par-m-chyma remaining healthy.

STATE OF THE PUBLIC HEALTH

SIR GEORGE NEWMAN'S REPORT*

It is sometimes forgotten by the public that the Ministry of Health concentrates the health services previously exercised not only by the Local Government Board but by the National Health Insurance Commission, and in the latter respect it controls a general practitioner service of enormous extent, engaging 16,500 practitioners in England and Wales, and entitling two-fifths of the population to medical benefit. In Sir George Newman's annual reports the two services—one represented by the medical officer of health and the other by the insurance practitioner—are not set opposite to one another, but are regarded as complementary. This British system has not only tradition but the balance of argument in its favour, and it derives noteworthy support from the Chief Medical Officer of the Ministry, who praises highly the medical service—which is a general practitioner service—afforded to the insured population. Not only is it vastly superior, he says, to the service given to the same class of people before the introduction of national health insurance, but the improvement in its content since the Act came in has been steady and continuous.

Three factors which are chiefly responsible for the rise in quality of the service are mentioned. In the first place, the Ministry of Health, in consultation with the Insurance Acts Committee of the British Medical Association, and, where necessary, with the approved societies, has sought to improve and simplify the conditions under which practitioners contract to provide advice and treatment. Secondly, the experience of the insurance medical service has developed in the members of the profession an appreciation, to an extent not previously attained, of their function as participators in a professional service for the public good. Finally, as a result of the progress of research, methods of treatment have been made available which, until recently, were unknown and unused, such, for example, as the treatment of diabetes by insulin, or of pernicious anaemia by liver extract.

THE "BOTTLE OF MEDICINE" HABIT

What the newspapers call a "story" might be written around the statistics of insurance prescribing. The people of England—the same does not apply to Scotland—are sometimes regarded as confirmed medicine drinkers. The bottle of medicine is looked upon by the working man, and still more by his spouse, as a necessary concomitant of medical attendance. Statistics show, however, that this habit of mind does not prevail to the same extent in all parts of the country. A table is given in the report showing, for every one of the 128 insurance areas in England, the average cost of prescribing per head of insured population in 1933. The list extends over a surprisingly wide area, from progressively thinking Manchester, where the average annual cost of medicines per insured person is very nearly five shillings, to "backward" Oxford, where it is below 1s. 10d., with London in a middle place, at just under three shillings. Even among districts in close geographical relationship there are surprising differences. Why should the cost in Gateshead be a shilling more than in Middlesbrough on the other side of County Durham, or in Essex a shilling more than in West Suffolk, or in Cambridgeshire a shilling more than in the Isle of Ely, or in Rutland 1s. 4d. more than in the adjacent Holland division of Lincolnshire? The population most thoroughly "physicked" is that of Lancashire and Cheshire, where in almost every household

in years gone by a regular item of expenditure was the doctor's bill, and an equivalent was demanded in the shape of something to be received not merely by the understanding but by the mouth. Traditional habit reflects itself in the prescribing statistics, and of the twenty most expensive prescribing areas eleven are in these two counties palatine.

It is easy to scoff at the bottle of medicine, just as Douglas Jerrold wrote of the pill as the daily bread of thousands. Sir George Newman pronounces a more considered judgement when he suggests that many practitioners give medicine in order to ensure that due regard is paid to their advice. It is not a question of sugar-coating the pill, but of using the pill itself as a cloak for counsel, which may be even more disagreeable to take. The prescribing doctor may have no greater faith in some of his medicines than the educated layman, but it is important that the patient should continue to come to him and heed what he has to say. Some doctors no doubt give a bottle of medicine fearing that they may otherwise lose their patients, but, at any rate where doctors work together with a reasonable understanding, there ought to be no difficulty on that score. A cantankerous patient may leave one doctor for another, but an equally cantankerous patient may at the same time leave the second doctor for the first, and possibly through these various transfers it may dawn upon the prescribed-for community at last that the important thing is not what they get made up at the chemist's, but the professional skill and care which is just as effective even when medicine is withheld.

THE CHIEF CAUSES OF SICKNESS

Another interesting sidelight on insurance practice is afforded by the result of the special investigation made of insurance medical records for 1933. A table is given showing the relative incidence of the chief causes of sickness for which insured persons consult their doctors. The number of practitioners whose records were investigated for this purpose was 825, and the insured persons for whom they were responsible numbered just over a million. Of the 77,180 cases attended during the year the largest number—nearly a quarter of the total—were cases of bronchitis, tonsillitis, nasal catarrh, and the common cold. Next came influenza, and after this the cases grouped respectively under diseases of the digestive tract, injuries and accidents, and lumbago and rheumatism. Only 548 of the cases (0.7 per cent.) were of tuberculosis in any form, and only 154 (0.2 per cent.) were of malignant disease. Indeed, the chief mortal diseases all take a low place in such a table. If these statistics are a reflection of insurance practice generally, out of every 100 patients he sees the practitioner comes across only about one having organic heart disease, one with anaemia, one with pneumonia, three with diseases of the genito-urinary system, five with skin diseases, six with diseases of the nervous system and special senses, and seven with abscesses, boils, and other septic conditions. "This demonstrates again," says Sir George Newman, "that morbidity figures have little direct relation in practice to mortality figures, and that while the general practitioner has on occasion to sign death certificates, his day-to-day work consists in the alleviation and cure of the less fatal ills of life, and staving off, with considerable success, the end which is in store for each of us."

INFECTIOUS DISEASES

The decline in the mortality of infectious diseases during the last thirty years has been remarkable. In 1933 there were only 2,646 deaths in England and Wales from diphtheria, 1,948 from measles—the lowest on record—and 729 from scarlet fever, although the total number of cases

* The first notice of the Annual Report for 1933 of the Chief Medical Officer of Health appeared in the *Journal* of September 22nd (p. 598).

of scarlet fever (129,528) was the highest for thirteen years. The prevalence of small-pox (*variola minor*) was very much lower than in the previous year, the number of cases being 631, as compared with 2,039, and for the first time since 1921 the year included one week in which no case of small-pox was notified. The number of deaths classified to small-pox was two. Enteric fever showed a large decrease—1,758 cases as against 2,544 the year before. Reference is made to the small outbreak in the North Riding of what is called in the report "epidemic myalgia" or "epidemic myositis," as described by Dr. W. N. Pickles' under the name "Bornholm disease." This was the first occasion on which the disease has been recognized in this country, though there is no doubt that it has been observed previously both here and in other countries, and recorded under various designations suggested by its cardinal symptom.

TUBERCULOSIS AND VENEREAL DISEASE

In dealing with tuberculosis Sir George Newman mentions that it is twenty-one years since a Departmental Committee was appointed under the chairmanship of Mr. (now Lord) Astor to consider a general policy in respect to the tuberculosis problem. Nothing in the experience of the subsequent period casts any doubt on the soundness of the lines of action laid down by the Departmental Committee on which the present national scheme for dealing with tuberculosis is based. To no one special factor in public health can the credit for the general improvement be assigned, but statistics prove that all forms of tuberculosis are declining. Immediately before the setting up of the national scheme the annual total of deaths in England and Wales from tuberculosis of the respiratory system was 38,000; the figure for 1933 was below 28,000; and the diminution in the number of deaths from other forms of tuberculosis within the same period has been even more remarkable. Yet there is still much to be done. In particular, more attention needs to be devoted to the examination of contacts, and a second problem is efficient after-care for the patient whose disease has been arrested by effective treatment. The medical supervision of such a patient may be fully arranged for, but often his home surroundings and his work cannot be satisfactorily adjusted to his physical condition. One disturbing feature is the rise of mortality in the industrial areas of South Wales at the ages from adolescence up to 35 years. Many of the social and geographical features of coal-mining districts favour tuberculosis: such as the loss of sunlight in the deep and narrow valleys in which the villages are situated, the tendency to crowd in small rooms and halls, the lack of playing fields, and, sometimes, an unsuitable dietary.

The venereal diseases scheme has now been in operation for eighteen years. In syphilis it has been attended by a considerable measure of success. Careful inquiries show that the majority of persons infected with syphilis resort to treatment centres, so that the returns from these centres are strong evidence of the trend of the disease, and the 1933 figure for cases dealt with for the first time (21,525) was the lowest yet recorded. There is no evidence of decline in gonorrhoea, and the incidence is likely to remain unchanged until either a specific remedy is found for the disease or the proportion of infected women applying for treatment increases very materially.

NEW OUTLOOK ON THE CANCER PROBLEM

The number of deaths from cancer recorded last year was 28,837 for males and 32,735 for females. As compared with the previous year the death rate for males decreased from 1,495 to 1,490 per million living, and the rate for females rose from 1,524 to 1,559. Since 1920, the

latest year in which the crude rates were modified as the result of war conditions, no similar instance of a fall in rate by comparison with the previous year has occurred for either sex.

Sir George Newman discusses the changing outlook in cancer prevention. It was a natural tendency when cancer became a subject of active experimental research to assume that such research would culminate in the discovery of some method of causation which would indicate a road to prevention. Opinion is moving away from this conception, in Sir George Newman's view, and it is now thought that the change in the character of the cells which have undergone malignant transformation is no more than a pathological, perhaps even a physiological, reaction to one or more of a wide variety of stimuli, more or less peculiar to the different organs affected. Such a change of conception brings about a definite alteration in the attitude towards measures of control. Previously it was thought wiser to await the result of research than to attempt measures of control which might be not only mistaken but wasteful. Now it is held that the hope of putting into application some general or universal method of prevention may have to be replaced by realization of the need for minute investigation of the abnormal conditions which precede or determine the emergence of cancer, conditions which probably differ widely in their nature for different organs of the body. The compiler of this report is alive to certain signs of discontent at the apparently negative character of the results of laboratory investigations for the solution of the cancer problem, as well as the comparative ineffectiveness of treatment on the mortality rate. Such an attitude of mind may easily be exaggerated. Laboratory research may not have discovered the "cause of cancer," but it has greatly contributed to a better understanding of the nature of the disease, and if the results of treatment are poor, at any rate it is encouraging to know that if conditions could be so modified that a majority, instead of a minority, of patients underwent treatment at an early stage, a higher curability rate would be secured. "Nevertheless, it is difficult to avoid receiving an impression of growing dissatisfaction with the rate of progress. . . . A similar feeling seems to be manifest abroad as well as at home." The future will probably reveal a tendency, says Sir George Newman, to concentrate more on clinical research. Incidentally this will give to national and regional radium centres a wider sphere of action. They might, by co-operating with voluntary and municipal hospitals and with practitioners, extend their functions to cover those of diagnostic centres and centres for research into all forms of treatment. The part played by local health authorities in the campaign against cancer is also likely to become even more important.

VOLUNTARY AND MUNICIPAL HOSPITALS

We began by mentioning Sir George Newman's reference to the general practitioner; we may close with his reference to the other great sphere of non-official medical service—perhaps the technical term should be "non-provided"—namely, the voluntary hospitals. He pleads again, with his customary eloquence, for co-operation between local authorities and the governing bodies and medical staffs of these hospitals. In most areas it should be possible, as it certainly would be advantageous, for the local authority and the voluntary hospital to agree on an arrangement whereby all patients requiring a particular form of treatment—especially treatment requiring expensive apparatus or materials or highly specialized skill—should be admitted to a particular hospital. "There is no reasonable cause of war between them [the municipal and voluntary hospitals]; there is cause only for marshalling them together for a joint war against disease."

¹ *Brit. Med. J.* 1933, November 4th, 1933 (p. 817).

MENTAL DISORDERS IN 1933

NUMBERS UNDER CARE

The twentieth annual report, Part I, of the Board of Control for 1933¹ shows that on January 1st, 1934, the number of persons suffering from mental disorder notified as under care in England and Wales was 150,266. This number is an increase of 1,491 during the preceding twelve months, which may be compared with the increase of 2,079 during the year 1932, or with the average annual increase for the five years ended January 1st, 1934, of 1,636. Were this diminishing rate of increase an index to the incidence of mental disorders in the general population favourable deductions might be drawn, but, as the Board points out, the yearly increases are merely the excesses of admissions over the combined deaths and discharges. Moreover, the numbers of admissions are affected by the amount of accommodation available in public mental hospitals, so that in some areas, notably in Lancashire, the true increase is larger than the Board's figures indicate because so many patients in need of active treatment have had to be retained in public assistance institutions for want of beds in mental hospitals.

Nevertheless, the Board is able to say that while the total number under care can never be a true index of the incidence of mental disorder, "the relatively small increase during the year affords some indication that the strain under which many have suffered has not been reflected in any increase in the number of new cases." The last few words are of significance, for it is the number of new cases, or, to be more precise, the ratio to the general population of the first admissions to mental hospitals and other institutions receiving "mental" patients, which furnishes the nearest approach to a true index of the incidence of mental disorder. This matter is not discussed in the present report, probably for lack of detailed information by the Board as to the movements—that is, admissions, discharges, etc.—of persons suffering from mental disorders in public assistance institutions and municipal hospitals. It may be noted in passing, however, that excluding these—and, after all, the county and borough mental hospitals receive over 80 per cent. of the whole mental patients in the country—the first admissions during 1933 showed an actual decrease of 629, there being 19,976 as compared with 20,104 in 1932.

Of the total of 150,266 patients under care on January 1st, 66,475, or 44.2 per cent., were males, and 88,791, or 55.8 per cent., were females. As to class, 8,428 males and 6,567 females were private patients, 57,383 males and 76,999 females were rate-aided patients, and 664 males and 225 females were criminal patients. The distribution of the 150,266 under care was as follows: 123,977, or 82.5 per cent. of the whole, were in county and borough mental hospitals and 230 in other premises of the local authorities; 2,422 in registered hospitals; 2,862 in licensed houses; 266 in naval and military hospitals; 830 in Broadmoor Criminal Lunatic Asylum; forty-two only were recorded as in nursing homes; 339 in private single care; 4,132 in outdoor relief; and 15,166 in public assistance institutions and municipal general hospitals.

It is interesting to note that while the rate-aided patients increased during the year by 1,692, the private patients decreased by 196 and the criminal patients by five. This actual decrease in the number of private patients—not merely a decrease in the rate of admission, notwithstanding the considerable separate provision now made for private patients in county and borough mental hospitals and the much-reduced fees charged by hospitals and houses solely for private patients—is significant of the hard times through which the country has been passing.

STATUS OF PATIENTS

Turning to the status of the 150,266 patients, 3,194 were voluntary patients, 226 temporary, and 146,846 certified. Of the voluntary patients no fewer than 2,015

were in county and borough mental hospitals, and of these 1,845 belonged to the rate-aided class, showing that this part of the Mental Treatment Act promises well. In "other premises" of the local authorities there were 230 more voluntary patients; in registered hospitals, 478; in licensed houses, 424; in private single care, eight; and in naval and military hospitals, one. Strangely enough, in nursing homes—that is, in nursing homes approved under the Mental Treatment Act—there were only thirty-eight voluntary patients under care on the first day of the year. The report does not give any indication of the numbers of nursing homes approved under the Act.

Of the temporary patients, of whom fifty-seven were males and 169 females, forty-six males and 116 females were in county and borough mental hospitals, the remainder being distributed as to thirty-two in registered hospitals, twenty-eight in licensed houses, and four in nursing homes. These numbers are disappointingly small, and show that, from whatever reason, the section of the Mental Treatment Act concerning temporary patients is being very inadequately worked. Thus the direct admissions during the year 1933 were 25,659 (males, 11,439; females, 14,220) and the proportions per cent. of these admissions arranged according to status were as follows: certified, 78.7; voluntary, 19.2; temporary, 2.1. Commenting on the fact, the Board says:

"Except in a few areas where special effort has been made the number of temporary patients in public mental hospitals remains disappointingly small. The total number of rate-aided temporary patients admitted during 1933 was 298. Private patients admitted on a temporary basis numbered ninety-nine. Excluding voluntary patients, the ratio of rate-aided to private patient admissions is ninety-seven to three. There is no reason whatever to suppose that the proportion of patients suitable for temporary treatment is any larger among private than among rate-aided patients. If the proportion of temporary admissions of rate-aided patients corresponded to the proportion among private patients, the total temporary admissions in the rate-aided class would have been approximately 3,280 instead of an actual total of 298. In other words, the non-volitional paying patient has about eleven times as good a chance of admission without certification as the rate-aided patient. An analysis of cases shows that only a fifth of the temporary admissions require to be certified subsequently, and it follows that in round figures 2,400 persons were certified in 1933 who might, if advantage had been taken of temporary treatment, have escaped certification altogether."

The report also shows that the procedure was not used in thirty-four of the county and borough mental hospitals, and was confined to less than 5 per cent. of the direct admissions in fifty-two hospitals, whereas at one or two named hospitals the proportions were from 10 to 17 per cent. and at one no less than 42 per cent.

MOVEMENTS OF PATIENTS

Owing to the absence of detailed information concerning the movements in public assistance institutions, etc., particulars of the patients in such institutions are not included in the Board's report on admissions, discharges, deaths, etc. Bearing this in mind, the following extracts show that the direct admissions to mental hospitals (25,659) gave a ratio of admissions per 10,000 of the population of England and Wales (aged 16 and upwards) of 8.47 (males, 8.01; females, 8.87), a decrease on the previous year of 0.02. If the voluntary patients are discounted, the ratio of admissions is 6.83 per 10,000 of population.

During the year under review 14,920 patients (males, 6,254; females, 8,666) were discharged or departed from statutory care as recovered, relieved, or not improved. Of these, 8,520 were discharged as recovered, yielding a recovery rate, calculated on the direct admissions, of 33.2 per cent. (31.7 for males, 34.5 for females). Patients discharged as relieved numbered 5,103, and as not improved 1,297. Deaths during the year numbered 9,408 (males, 4,385; females, 5,023), giving a death rate, calculated on the average number daily resident (129,712), of 7.3 per cent. as compared with 7.6 for the previous year.

¹ The Twentieth Annual Report of the Board of Control for the Year 1933. Part I. 1934. London: H.M. Stationery Office. (2s. net.)

ACCOMMODATION

The report states that despite financial difficulties satisfactory progress has been made in the development of the mental health services, and so far as public mental hospitals are concerned the position has distinctly improved. The aggregate number of patients in excess of accommodation in these hospitals has fallen from 1,717 on January 1st, 1933, to 843 on the first day of 1934. To a considerable extent this improvement is due to the new Middlesex hospital at Shenley, to which patients began to be admitted on January 1st, 1933. But although in general the shortage of beds which two years ago caused grave anxiety has now been materially reduced, in particular areas there is still overcrowding.

Referring to the boarding out of patients from mental hospitals the report says that "though the number of patients suitable for boarding out is necessarily limited, probably not much more than 5 per cent. and certainly less than 10 per cent. of the total, we regret that more extended use is not made of a form of care which is economical. It saves capital expenditure, and, if the patients are wisely chosen, is beneficial to the patients, since it enables them to live a more normal life than is possible within the curtilage of a mental hospital." An experiment, we learn, is being made in East Suffolk in boarding out from the mental hospital. At the end of the first six months twenty-five patients, elderly women, some of whom had been in the mental hospital for over twenty years, were placed out in the care of sympathetic and capable women guardians. The experiment is still in its early phases, but the Board says that it has been shown beyond doubt that even patients who are thoroughly institutionalized do appreciate and respond to normal surroundings and home life, in which, with hardly any exception, they have rejoiced. This may very well be the beginning of a widespread movement in favour of a system the benefits of which, as a supplement to hospital treatment, resulting in an increase in happiness and health to patients, a lessening of the burden on the public, and the release of hospital accommodation for cases urgently in need of it, were emphasized in this *Journal* as long ago as 1905.

OUT-PATIENT CLINICS

Of outstanding interest is the Board's report on the centres or clinics for the out-patient treatment of nervous and mental disorders, most of which have come into being since the passing of the Mental Treatment Act. While appreciating the valuable out-patient work of the mental hospitals themselves and at such centres as dispensaries and municipal offices, the Board describes the growth of clinics for the treatment of mental illness which form sections of the out-patient departments of general hospitals, and at which at least a share of the treatment is directed by members of the mental hospitals' staff. During the five years 1925-30, and excluding the London area, the twelve voluntary general hospitals thus linked to mental hospitals grew to twenty-five, and during the first year's working of the Mental Treatment Act thirty-five more were added. At the end of 1931 there were sixty-one general hospitals linked up for the purposes of out-patient treatment of mental illness with forty-nine mental hospitals, and at the close of 1933 there were eighty-five general hospitals linked up with sixty-seven mental hospitals. The methods and frequency of sessions vary in the different centres, and for this reason the report contains brief accounts of twelve separate clinics, their constitutions, attendances, and so on. It may be noted, however, still excluding London, that 10,000 cases were treated at these out-patient clinics during 1933, and that the attendances numbered 45,000. "Evidently," the Board continues, "another substantial step forward has been taken, and we believe that we have reached a stage at which adequate facilities for the out-patient treatment of nervous and mental diseases should properly be regarded as an essential and normal part of an area's mental health service."

MENTAL DEFICIENCY IN 1933

The mentally defective patients under care on January 1st, 1934, numbered 70,764 (males; 35,835; females, 34,929), giving a net increase for the year 1933 of 4,871, or for the ten years 1924-34 of 28,467. Included in these totals are the patients under statutory supervision, and those under guardianship or notified, who numbered 31,921 and 3,049 respectively.

The annual returns furnished by local authorities to the Board show that on January 1st, 1934, the number of defectives, whether "subject to be dealt with" or not, reported to these local authorities was 106,439, giving an increase over the preceding year's figures of 4,094. The growth in numbers and ratios to population in the defectives of whom the local authorities have taken cognizance during the decade 1924-34 is shown in a table, according to which the ratio per 1,000 of population has risen from 1.46 for the period 1924-6 to 2.65 for the period 1932-4.

This last ratio of 2.65 may be compared with the estimate of the Wood Committee of 4.52 per 1,000. Of the total number (106,439) reported to the local authorities, 78,438 (1.95 per 1,000) were reported as "subject to be dealt with," and of these 11,100 were in receipt of poor relief, including 4,018 receiving outdoor relief. This last fact is the subject of comment by the Board, which urges all local authorities to give the matter their serious consideration, since there are many reasons why financial help, if needed by mentally deficient persons, should be given through the mental deficiency rather than the public assistance committees.

The Board draws attention to a disquieting decrease in the number of children notified by local education authorities, and also to the fact that when mentally defective children leave ordinary schools (not special schools or classes) on attaining the age of 14 the local education authorities have no power to notify, while the mental deficiency authority has no power to act until the child is 16. There is thus a gap of two years to be bridged, possibly by amendment of the Act. It may be hazarded that the consequences of this hiatus would be much less serious if a common standard of "mental deficiency" were accepted by the two authorities.

The event of the year was the opening of the Hertfordshire colony for mental defectives at Cell Barnes with 600 beds. This is the second complete colony to be opened by a local authority, Hortham being the first. The actual cost of building (£299 a bed) is much below that of constructing a mental hospital. The total number of beds provided during the year was 2,254, and the Board says that steady progress is still being made in providing institutional accommodation for defectives.

DEFECTIVES IN MENTAL HOSPITALS

For many years mental hospital authorities have hoped that the operation of the Mental Deficiency Act would result in the transference of mental defectives in mental hospitals to mental deficiency colonies or institutions, thus restoring considerable numbers of hospital beds to their proper or better uses. The results of an investigation into this matter at certain mental hospitals is therefore of much interest and importance. The mental hospitals were Barming Heath, Chatham, Cheddleton, Stafford, Burntwood, Suffolk, Ipswich, Bridgend, Cardiff, and Swansea. The examination of the patients, who were selected by the medical superintendent as *prima facie* defective, was carried out by two medical commissioners of the Board. In all 2,007, or 17 per cent. of the total number of patients in these hospitals, were examined individually. Of these 1,692, or 14 per cent., were found to be mentally defective. Obviously not all could be expected to be fit for transfer to care other than provided in mental hospitals. But this indication that at least 12 per cent. of the patients in mental hospitals are suitable for transfer to mental deficiency institutions undoubtedly has an important bearing on the provision of mental hospital accommodation throughout the country as a whole.

INTERNATIONAL HEALTH WORK

[FROM OUR GENEVA CORRESPONDENT]

The praises of the Health Organization of the League of Nations have again been sung in the present Assembly. Delegates from a score of countries paid earnest tribute to the work done. The chorus was led by M. Borberg, Minister of Public Education for Denmark, who emphasized the important achievements in the field of biological standardization. The work of the second conference, held in London in June, he said, would be very useful to factories marketing vitamin products, as well as to the official laboratories engaged in inspection. The Commission on Biological Standardization, meeting in August in Copenhagen, had done some practical work by adopting for international use standard preparations and potency standards for the anti-gangrene, anti-pneumococcus, and anti-staphylococcus serums.

RURAL HEALTH SERVICES

Dr. Broekhuisen, the South African Minister at The Hague, mentioned that next year a conference is to be held at Capetown to discuss sanitary and medical services in rural districts, the health of natives and organization of medical services on their behalf, protective measures against the introduction of yellow fever, and prophylactic measures against plague and other diseases. South Africa, he said, attached great importance to this conference, and hoped that it would be pan-African. Sir Homi Mehta, the Indian delegate, acclaimed the pan-African congress as of great interest to India, which had participated in a previous congress at Capetown, and Mr. G. H. Shakespeare, M.P., for the United Kingdom, promised the support of his Government. Mr. Shakespeare also mentioned the value of collective study tours, such as that made in Poland in 1933, and thanked the director of the Health Organization for having organized a tour which would shortly enable British doctors to study the construction and arrangements of hospitals in other countries.

The malariological course recently organized at the Institute of Malariology at Rome was mentioned by Senator Cavazzoni of Italy, and M. Raphael spoke of the help rendered by the Health Organization to Greece in reorganizing its health services. He mentioned that Dr. Norman White had given five years' service to that country, and said that his name would always be linked with the creation of the School of Health, of which he had been a director. Professor Djuvara, from Rumania, said that the Health Organization had carried out in his country a number of studies and inquiries of the greatest scientific and practical interest. He mentioned particularly a study of the comparative efficacy of synthetic remedies and of quinine in the treatment of malaria. The Health Committee had sent Dr. Akroyd to Rumania to study, in collaboration with the Rumanian authorities, the problem of pellagra, and this collaboration was already bearing fruit. An experimental research centre had been opened near Jassy, and a fall in the incidence of the disease had already been observed among the groups of populations subjected to experiment. From Czechoslovakia M. Kunz-Jizersky bore witness to the co-operation of the Health Organization with his Government in endeavouring to raise the standard of public health in Slovakia and sub-Carpathian Russia.

General Tanczos, the Hungarian delegate, referred to the usefulness of the study of rural health services. Hungary was co-operating in inquiries concerning the possible effects of the economic depression on health and nutrition, the Home Office in that country proposing to carry out an inquiry into the state of nutrition of 1,000 families living in rural districts. Dr. Pedro de Alba of Mexico mentioned large sanitary undertakings in his country in the shape of waterworks and drainage schemes, in which useful advice had been forthcoming from the Health Organization; and Dr. Chodzko, a former Minister

of Health for Poland, emphasized the importance of the Epidemiological Bureau, and the great medical, social, and commercial value of accurate news of epidemics.

Then came the representative of the Irish Free State, who said that his Government had drawn up a programme on which it was necessary to obtain technical advice of the highest quality. It had accordingly appealed to the Health Organization, which at once made a study on the spot of the problem to be solved. At the present moment the public health authorities in the Free State and the Health Organization of the League were co-operating in framing a scheme of rural hospitalization, and there was every ground for hope that a scheme would be created which would later serve as a model for other countries. M. Jules Gautier of France congratulated Dr. Rajchman, the head of the International Health Organization, on the fact that the organization had remained intact and was even expanding, notwithstanding the decrease in its financial resources. Representatives of China, Venezuela, Canada, and other countries were similarly complimentary, and a resolution was unanimously carried noting with satisfaction that the Health Organization had ensured the continuity of its essential work while adapting its activities in such a way as to take account of existing economic and financial conditions.

SMALL-POX IN 1933-4

The July-August issue of the *Epidemiological Report of the Health Section of the League of Nations* contains, as it did last year, an informative alphabetically arranged survey of the recent incidence and mortality of small-pox throughout the world.

Egypt, in which there were 5,697 cases with nearly 1,000 deaths, was one of the most important foci in Africa. The disease was not uniformly and simultaneously present in every province, but followed an independent course in each. In 1934 the disease showed a definite decline, the number of cases in May and June being about one-fifth of those reported during the same months of 1933. In Central and East Africa there was a progressive decline in the disease in Tanganyika Territory and Nyasaland, whereas in the Belgian Congo the number of cases rose considerably, although the mild form predominated. In Morocco the small-pox endemic has considerably declined, and in Algeria and Tunisia the number of cases remains extremely low. As regards America, small-pox is on the decline both in Canada and in the United States where the disease is rare in the densely populated States of the north-east, relatively high in the centre and south, and highest in the States of the Pacific and mountain areas. In Mexico, though it is on the decline, small-pox still causes thousands of deaths each year. In Asia, British India, in which the number of cases recorded rose from 115,000 to 250,000 in 1933, continues to be the primary focus, the increase being due not to any severe local epidemic, but to general spread of the disease. In China small-pox was frequent at the ports, especially Canton, Shanghai, and Hong-Kong, in 1933, and increase in small-pox incidence also took place during the first part of 1933 in Manchuria, Chosen, and Japan. In Persia small-pox incidence was considerably lower in 1933 than in 1932, and in 1934 than in 1933.

In Europe the most important foci, as in the previous year, were Soviet Russia, where the disease was of a severe type, but showed a lower incidence in 1933 than in 1932; Spain, where there was a marked fall in the morbidity in 1933 as compared with previous years, and the disease is mainly of the mild type; Portugal, where the mortality rate was 29.4 per cent. in 1933; and England and Wales, where only 631 cases were recorded in 1933, and 174 in the first six months of 1934. With the exception of an outbreak of variola major originating abroad, which caused twenty-four cases and three deaths at Blackburn between January and March, 1934, all the cases in England and Wales were of the mild type. As in the previous year, there were no cases in Australia, New Zealand, and the Pacific Islands in 1933 and the first half of 1934.

British Medical Journal

SATURDAY, OCTOBER 6th, 1934

ANTE-NATAL CARE AND OBSTETRIC DIPLOMAS

The recent discussion at the Bournemouth Meeting of the British Medical Association, on the results of ante-natal care, held jointly by the Sections of Obstetrics and Gynaecology and of Public Health,¹ rendered a public service by focusing attention not only upon the failure of ante-natal work to reduce maternal mortality but also upon the lack of order and of uniformity in this branch of obstetric service. Throughout the discussion there appeared to be tacit acceptance of the view that public health workers as well as obstetricians are deeply concerned with the problems for which a solution must be found before a national midwifery service can be organized on a durable and practical basis. The ideal that the mother should be under the care of the same individual medical attendant throughout pregnancy, labour, and lying-in received general acceptance; nevertheless it is at present realized only in exceptional circumstances, apart from private practice. Even in teaching hospitals and in the chief maternity hospitals the ante-natal clinic is usually conducted by junior officers who are not in charge of wards. The municipal hospitals are mostly in similar case. The mother has passed through the hands of three medical attendants, or it may be three sets of attendants, when she finally reaches the combined infant welfare and post-natal clinic. It is clear that considerable rearrangement will be necessary if the ideal of continuous individual supervision is ever realized in hospital practice, and it is to be remembered that the number of women who enter hospital for their confinement is continually increasing.

Of equal importance to organization is the attitude and outlook of the medical attendant. During the Bournemouth discussion it was acutely observed by Dr. Ethel Cassie that "the obstetrician making himself responsible for ante-natal care should be as much a physician as a surgeon." The surgical bias which has in recent years been so much in evidence in obstetric teaching and practice is not an unalloyed benefit. Arising doubtless from the desire to apply surgical methods of antiseptics to midwifery, it has carried many of its adherents to the point of regarding the conduct of labour more and more as a surgical problem, to which surgical—that is, operative—methods can safely be applied. Herein lies apparently the most important cause of the great increase in recent years in the proportion of operative deliveries reported from all parts by obstetric writers. The too surgically minded obstetrician does not visualize midwifery as a branch of preventive medicine; believing that he can safely

cut his way through difficulties should they arise, the temptation to set little store by prevention is often irresistible. Nevertheless, it is undeniable that in ante-natal work a knowledge of medicine is of greater importance than the possession of surgical technique.

The ideal obstetrician, whether specialist or general practitioner, should be a man of wide and level outlook. There is something to be said for the view expressed at Bournemouth by Dr. G. F. Buchan that the obstetric service requires a new kind of specialist whose function would be "ante-natal care in its widest sense," the management of labour, and the "care of the mother and child for a period after birth." Specialists whose interest is divided, often very unequally, between gynaecology and midwifery, whose medicine has become rusty from disuse, and whose knowledge of the principles of infant care is elementary, are not fully equipped to take a controlling part in the ante-natal service of the country. This view was probably present in the minds of the advisers of the Society of Apothecaries of London when they established their mastership of midwifery, for they demanded evidence of post-graduate training not only in midwifery but also in infant management and in certain aspects of public health work; and, further, they obtained the assistance of representatives of public health and of paediatrics, as well as obstetricians, in conducting their examination. The Apothecaries' Society, in short, foresaw the need for the type of specialist which Dr. Buchan adumbrates. It is to be regretted that the two other obstetrical diplomas which have been launched since the mastership, of the Apothecaries depart more or less widely not only from their fore-runner but also from one another. It is a disservice to have three specialist examinations in midwifery based upon different views as to the training required of those who aspire to be entrusted with responsibility in the obstetric service of the country. If the three bodies concerned could agree upon basic requirements and formulate a joint scheme, the position would be greatly simplified for those who desire recognition, not as specialists, but as practitioners well equipped to deal with responsible obstetric work.

RESISTANCE TO INFECTIVE DISEASE

The science of genetics maintains a vigorous growth, and eugenics, as a social creed, does not lack prophets or disciples. No one, we may suppose, would seriously contemplate an attempt to deal with human disease in the foreseeable future by the elimination, along eugenic lines, of susceptible individuals, even if the laboratory worker had demonstrated beyond cavil that the adventure would be a hopeful one. But the same considerations do not hold in regard to our animal herds, from which man is so frequently infected. The breeding of a strain of cattle solidly immune to tuberculosis, or to bovine abortion, or to foot-and-mouth disease, might

¹ *British Medical Journal*, August 4th, pp. 193-201.

be a project well worth serious consideration, if it could be shown to have any reasonable chance of success; and the results already attained along these lines in the virus diseases of plants suggest that it would be unwise to dismiss such a line of attack as inherently impracticable. Whether we approach the problem from the purely scientific angle, or with utilitarian possibilities in view, the first step is clearly to consider the evidence, and, if it justifies no verdict one way or the other, to set about collecting data of a fuller and more reliable kind. An admirable monograph by Dr. A. Bradford Hill, published in the Special Report Series of the Medical Research Council,¹ goes far to fulfil the first of these requirements, and so to allow us to form a reasoned judgement on the problem as it now presents itself.

That one animal species differs from another in its resistance to a variety of pathogenic parasites has long been known, and there can be no reasonable doubt that individual differences in resistance within a single species are due, in some part at least, to differences in genetic make-up. The existence of heritable differences in immunity, and the possibility of developing by selective breeding a strain that has a resistance greater than the average to some particular bacterium or virus, may be safely assumed. The problems at issue, as Dr. Hill emphasizes, are to assess the degree of resistance attainable along these lines, to determine whether it operates specifically, so that each important infective disease must be regarded as a separate exercise in eugenics, or more widely, so that we might reasonably hope to develop strains that would be immune to many of the infections that plague their unselected fellows, and, in particular, to obtain some measure of the relative efficacy of genetic selection as compared with natural or artificial immunization.

To almost all the questions that he asks he has to return the verdict "non-proven." The experimental data, on which alone a sound judgement can be based, are in practice extremely difficult to obtain. The obvious experimental method is to infect an adequate sample of animals with the micro-organism under study and breed from the survivors, repeating this process in each succeeding generation; and this is the line of procedure that has most commonly been followed. But it overlooks the awkward fact that the breeding stock is in this way infected *ab initio* with the organism concerned, and that congenital transmission of passive immunity from the infected does, and active immunization of their offspring by infections of varying severity, will be operative to an unpredictable degree. Several workers have simply ignored this difficulty, so that their conclusions are invalid. Others have striven to overcome it, sometimes with considerable success. Dr. Hill concludes that the more carefully planned experiments leave little doubt that a true genetic immunity can be developed, though the possibility of active im-

munization can seldom be excluded with complete certainty.

The grade of resistance that can be developed by selective breeding is, however, very difficult to assess. Several workers have listed as "resistant" animals whose only claim to that title was that they took rather longer to die of the test infection than unselected controls. Where the test has been the survival over a reasonably long period of a proportion of the infected animals the difference between the selected and unselected groups has often been small, though in a few instances it has been very large. Another puzzling feature of some of the records is the absence of an increasing resistance as one passes from one generation to the next through a long series of matings. It would appear, so far as these particular experiments are concerned, that a considerable increase in resistance in the first or second selected generation may be followed by no further improvement when the selective breeding is continued. In other instances the records show a continually falling mortality rate with increasing selection over a number of generations; but there is no evidence that, by selective breeding, a strain can be developed that is uniformly resistant to infection, even when the test of resistance is a single injection of the bacterium under study in a dose that fails to kill 100 per cent. of the controls.

In regard to the question of specificity the evidence is still more conflicting. Certain observations have been interpreted as indicating a genetic immunity operating over so wide a range that it is effective against a pathogenic bacterium, such as the mouse-typhoid bacillus, and a poisonous metallic salt, such as mercuric chloride. But many other experiments have given results that accord ill with this view, and indeed it seems inherently improbable if it is generalized to include genetic immunity as a whole, though it is reasonable enough to suppose that some genetic factors may determine characters that increase resistance to a considerable variety of harmful agents. It is probable, as Dr. Hill points out, that a large number of factors are involved, and that some of these may act non-specifically while others may be specific in the strictest immunological sense. The determination of the genetic characteristics of an animal in relation to its susceptibility to infection is, indeed, never likely to be a simple problem, for the protective mechanisms employed by an animal host are multiple and diverse. But the fact that a problem is difficult does not mean that it is insoluble, or that its solution is not worth attempting, and the particular merit of Dr. Hill's review is that it points out clearly and in detail why it is that many workers have failed to get significant answers to the questions they have asked, or thought they were asking, and indicates the lines along which further experiments should proceed if significant data are to be obtained. The author and the Medical Research Council are to be congratulated on a valuable contribution to the literature of an intrinsically important subject.

¹ The Inheritance of Resistance to Bacterial Infection in Animal Species. Medical Research Council, Special Report Series, No. 196. London. H.M. Stationery Office. 1934. (1s. 3d. net.)

WHITHER MEDICINE?

Dr. Josef Loebel is of opinion that people complain that medicine is not progressing simply because it has progressed so rapidly that they themselves have been unable to keep pace. This is encouraging, and stimulates us to ask with him "Whither Medicine?" Can we learn from the past what the future of medicine is likely to be? This Dr. Loebel has attempted to do in a semi-popular style.

Though Hippocrates converted medicine from a magical cult to a method of observation, magic would keep "breaking through" again and again. Largely this is because the sick man craves for magic as his far-off ancestors did, but partly it is because up to the nineteenth century the doctor had so little apparatus to aid his observation. He must have depended mainly on mother wit and shrewd intuition. His cures must have emanated chiefly from his own personality, as indeed they still do in some degree. Osler used to ask students by what means a patient suffering from cancer of the stomach might be induced to gain 20 lb. in weight, and had to supply the answer himself: "The only way of working the miracle is to have an optimistic doctor." With the introduction of cellular pathology, humours and diatheses were relegated to the limbo of superstition. Virchow declared that "there is no such thing as a sick body that is disordered in all its parts. I maintain that no doctor can systematically think of a morbid process unless he is able to assign to it a place in the body." The part became for him greater than the whole. But with the discoveries of serology and endocrinology, humoral pathology and diatheses came creeping back, though with new and more scientific attributes. The individual again began to count for something. As Dr. Bernard Hart has said, he was no longer regarded as "the uninteresting vehicle of a fascinating disease process." Still more did this become true when "the breach was made in the Great Wall of psychology by doctors." One might claim, though the claim would be fiercely resisted in academic quarters, that psychology has gained as much from medicine as medicine has from psychology. Yet it is true that the dualism of mind and body has broken down under the assaults of psychologically minded physicians, and disease and unhappiness alike can be seen as the resultant of forces in the individual and his environment. The psychiatrist and the biochemist can find a common meeting ground in the fact—long suspected, but now, as a result of Sir Henry Dale's work, capable of being enunciated as a general law—that all nervous mechanisms produce their effect through the intermediary of chemical substances. This new synthesis of mind and body, this conception of the individual as a dynamic entity, is the outstanding achievement of twentieth century medicine, and will greatly influence its future.

These are reflections aroused by Dr. Loebel's book rather than a paraphrase of its contents, though we

have quoted some salient passages. The author has evidently enjoyed writing it, and succeeds in conveying that enjoyment to the reader. His enthusiasm for his subject makes one lenient towards the somewhat journalistic manner in which he presents his case; but it is a pity that he has allowed certain inaccuracies to creep in. Thus artificial pneumothorax is not an adaptation of war-time gassing, nor does a good climate depend on the air containing plenty of oxygen. The oestrogenic substance in coal did not get there thousands of years ago from the bodies of women—the coal measures are older than Eve. It is not correct to say that the importance of the parathyroid glands has not been discovered at all yet. Do any morphologists to-day regard the invertebrate nervous system as surviving in the sympathetic nervous system alone? Scrotal secretion is not a happy description of the treatment Brown-Séquard employed on himself, and one can hardly agree that St. Francis of Assisi was "gloomy by temperament." When Dr. Loebel quotes the late C. B. Lockwood as saying "that it was unnecessary for a surgeon to clean his nails before operation, because a gentleman does that sort of thing at home," we fear that he was misled by Lockwood's sardonic humour in taking this as evidence that he was opposed to antiseptics. For it is certain that he made a practice of having cultures taken from clippings of the nails of all those whose hands came into the operation area, and was a convinced advocate of a rigid aseptic technique.

RADIOLOGISTS AND HOSPITALS

In the *American Journal of Roentgenology* for July there is an important editorial article dealing with the position of radiologists, and incidentally with that of clinical pathologists, in relation to hospitals. It contains a clear statement of the principles that should govern those relationships, and may usefully be compared with the two appendices, G and H, in the Hospital Policy of the British Medical Association, which are concerned with the same matters. Hospital developments in America, and, in general, developments of what is called the "corporate practice of medicine," are not on exactly the same lines as those in this country; but there can be no difference in the principles in accordance with which progress should be guided and encouraged. The enunciation of these principles and the statement of the methods by which they should be carried into effect in connexion with radiology and chemical pathology were found by the Hospital Committee and the Council of the B.M.A. to be matters of great difficulty. Their consideration occupied much time over a period of several years, though ultimately the paragraphs of the appendices above mentioned were generally agreed to and have, in fact, so far as they have become operative, worked reasonably well. No doubt before very long they will be the subject of revision and may be found to require modification, and in this connexion a clear statement of the American position and a careful study of American experience will prove of value. The exploitation of service in the two fields under considera-

¹ *Whither Medicine?* By Dr. Med. Josef Loebel. Translated from the original German by L. Marie Sieveking and Ian Morrow. London: Sidgwick and Jackson Ltd. (7s. 6d. net.)

tion, whether as commercial ventures by business organizations, or by universities, hospital boards, and local authorities, is a real danger both to the legitimate development of private practice in these directions and to the independent and scientific status of radiologists and pathologists as members of the staffs of hospitals. As the article under notice says: "We have a right to expect the entire profession to uphold the pathologist and radiologist in their efforts to remain free practitioners of medicine. Any other course can result only in damage to both the profession and the public"; and again: "That other branches of the profession now feel comparatively safe is no reason why they should remain inert or actually assist hospital corporations to take over and control these particular specialties." Alarm is expressed in the article at a recent proposal to separate the technical aspects of radiology from its professional aspects, the hospital being responsible for all that pertains to technique and making an appropriate charge therefor, while the medical radiologist charges his fee for his professional services. Surely, however, as a financial arrangement there can be no fundamental objection to such a method. It is, of course, true that the technical part of the work is essential to the success both of the radiologist and of the pathologist, and that this has been brought to its present state of development only by constant interest and attention; but the essential thing to be safeguarded is that the professional standing of the head of the department should be fully recognized and his complete control over the working of his department guaranteed.

NEW DRUGS FOR OLD

The annual report of the American Medical Association's Council on Pharmacy and Chemistry,¹ to which we referred on August 4th (p. 217), is of interest, since it provides a convenient summary of recent advances in proprietary drugs. Advertisements of these drugs descend upon the doctor's breakfast table with the steady persistence of falling snow, and most of the recipients must wonder from time to time what real therapeutic advance is represented by all this activity. The A.M.A. publishes annually a volume entitled *New and Non-Official Remedies*, and preparations are only admitted to its pages if they comply with certain simple though searching requirements. Some of the chief specifications are that there must be no secrecy associated with the preparation; it must represent a genuine therapeutic advance, and the claims made for it must be reasonable and supported by adequate evidence. These rules are well known, and hence only preparations of a certain standing are likely to be submitted to the council which has the duty of deciding their fate. An analysis of the table of contents of the report makes interesting reading. It was decided to admit in future antipneumococcus sera containing Type II antibodies, which had been omitted in 1924, judgement was suspended on six articles, and about fifty others were declared non-acceptable. At the same time it was decided to omit ten articles that had been accepted in previous years. This summary suggests pessimistic conclusions regarding the probable value of new pro-

prietary preparations. It must be mentioned, however, that the group on which judgement was suspended is important, since it includes the oestrogenic hormones, dilaudid and fuadin. The A.M.A. report states the results of an impartial but critical estimate of the value of a large sample batch of new proprietary articles, and these findings suggest that the odds against such an article representing a serious therapeutic advance are somewhere about 100 to 1.

CEREBRAL CORTEX AND GASTRO-INTESTINAL MOTILITY

The localization of the cortical areas controlling peripheral functions and activities always presents a fascinating problem to the neurologist and physiologist. Whereas, however, our knowledge of the cortical representation of motor and sensory functions associated with the cerebro-spinal nervous system is very extensive, it is much less so in the matter of the autonomic system. Much has been done in tracing controlling centres of autonomic function in the region of the hypothalamus, but cortical representation is still only vaguely understood. The matter of cortical control of intestinal movements has recently been reopened by Watts and Fulton.¹ In their article these authors give a short but interesting account of former work in this field. As long ago as 1876 Bochefontaine found that electrical stimulation in the region of the dog's sigmoid gyrus usually diminished or completely inhibited gastric rhythm, but sometimes this inhibition was preceded by strong peristaltic movements. These results seem to indicate that there are both motor and inhibitory cortical points for the stomach. Later work by Hlasko also gave evidence of inhibitory points in the cortex, and, in addition, he obtained contraction of the stomach wall by stimulation in the region of the corpora quadrigemina. Several workers have found that decerebration posterior to the thalami produces very active peristalsis in the cat's intestine, again indicating the probable existence of inhibitory control in the cortical regions (the question of irritation through the section could be ruled out). In 1888 Pal and Berggrün observed that stimulation of the vagus produced contraction of the pylorus but only slight peristalsis of the small intestine; on cutting through the medulla and then stimulating the vagi, vigorous intestinal peristalsis occurred even when, as we now know, the irritation from the transection had certainly passed off; indeed, the authors state that stimulation of the vagi immediately after the transection did not lead to a positive result, which they interpreted as due to irritation of the inhibitory fibres. The inhibitory influences could also be removed by section through or anterior to the thalami or by extirpation of the sigmoid gyri. This and other work made it probable that the cortex was mainly concerned with inhibition of the gut movements. Watts and Fulton were led to a consideration of the problem from the fact that routine post-mortem examination of a series of monkeys which had been subjected to various brain operations revealed an usually high incidence of intussusception. Three healthy monkeys died with intussusception and obstruction after bilateral removal of the anterior portion of the pre-motor cortex: the incidence of intussusception in unoperated monkeys was

¹ American Medical Association, 535, North Dearborn Street, Chicago, 1934.

¹ *New England Journ. Med.*, Apri. 26th, 1934.

two out of 300 necropsies. Faradic stimulation of the pre-motor cortex led to active intestinal peristalsis, and in some cases to well-marked multiple intussusceptions. Intermittent stimulation of the same cortical region over a period of several hours also resulted in intussusception. Application of the stimulating electrodes to the motor cortex itself led, of course, to vigorous muscular responses but did not influence the intestinal movements, a common observation and one readily to be inferred from the fact that cortical centres for the gut have not been previously localized. The more or less reciprocal functions of the gut wall and the sphincters were demonstrated in that pre-motor stimulation at certain points relaxed the stomach sphincters. Section of the vagi prevented the formation of intussusception during pre-motor stimulation, but some increase in peristalsis still occurred—a point of very considerable interest. Thus these workers demonstrate that intussusception may result both from removal of the pre-motor cortex and from stimulation of this area. The conclusion seems justified, therefore, that the gut has autonomic representation in this part of the cortex, and that this representation includes both excitatory and inhibitory components. The pathways of excitation and inhibition have not yet been worked out, but the classical view of the vagi and the splanchnics is not likely to be assailed. What may accrue is the existence of additional pathways and possibly association paths between the higher centres and the intestinal centres. Perhaps even some explanation on anatomico-pathological grounds will be forthcoming of the extraordinary restriction of intussusception to children of less than 5 years and its much greater frequency in males.

WELFARE OF THE BLIND

The eleventh report of the Advisory Committee on the Welfare of the Blind to the Minister of Health deals with the year 1933-4.¹ The number of blind persons in receipt of pensions under the Act of 1920 shows a steady increase from year to year, and the cost of these pensions is now £553,000 per annum. Reference is again made to the need for securing, before a person's name is added to the register, an examination by a medical practitioner with special experience in ophthalmology, and by him certified to be blind within the meaning of the Blind Persons Act. So far, as a result of representations by the Minister, thirty county councils and sixty-seven county borough councils have made provision for expert examination before registration, and it is understood that thirty-eight others follow the same practice. The supervision of the work done for the blind is now in the hands of the local authorities under the Act of 1929. Before the coming into operation of that Act the inspectors of the Ministry were responsible for systematic inspection of the work of the voluntary associations. The local authorities must now satisfy themselves as to the efficiency of the services towards the cost of which they have to contribute. In many cases an officer of the local authority exercises the supervision. In the area of the Northern Counties Association a regional supervisor appointed by that body is acting for nearly all the local authorities. This officer is engaged upon a detailed inquiry

into the administration of the work of the voluntary associations, drawing attention to any defects and making recommendations for improvement to the appropriate local authority. By this means the local authorities of the area obtain the advice of a specialist in supervising their services for the welfare of the blind. The register of the blind showed a total on March 31st, 1932, of 62,079. At the same date 1933, the figure was 63,408, of whom 244 were under 5 years of age and 2,089 between the ages of 5 and 16 years. The increase is in the later adult years.

INDUSTRIAL HEALTH RESEARCH

The fourteenth annual report of the Industrial Health Research Board¹ indicates that steady progress is being made in most of the lines of investigation described in previous reports, but it is pointed out in the introduction that in the Board's work more stress is now being laid on problems of health and mental fatigue, while researches relating to the physical fatigue induced by the expenditure of excessive muscular energy in heavy industries are less prominent. In order to make adequate studies of the kind of ill-health to which the workers in various occupations are liable, it is important to obtain physiological data about the normal physical fitness of the population. This is by no means easy. The workers are apt to object to examination, as they are afraid that the discovery of physical unfitness may lead to dismissal or to reduction of compensation under the Workmen's Compensation Act. Again, the sickness-recording systems under the National Health Insurance Act leave much to be desired from the point of view of the scientific worker. The numerous approved societies frequently do not know the occupations of their members nor the factories where they are employed. Nevertheless, it has been found possible to get reliable data in certain specific instances in the cotton and printing industries, while inquiries are now in progress into the alleged high incidence of gastric disorders among bus drivers, and of the effect of dust inhalation on haematite ore workers. An extensive survey of the physique of women has already been published, and one on the height, weight, and strength of a group of 10,000 men—including a sample of unemployed—has now been completed. The investigations on mental fatigue include extensive inquiries into the factors producing contentment and efficiency in women engaged on repetition work, with special reference to the reactions of character and temperament to the boredom entailed by such work. A large number of workers engaged in continuous production on conveyors have been observed, and have been tested by individual interview. Boys leaving school, Royal Air Force apprentices, and men in the Royal Corps of Signals and other branches of the Defence Services have been examined from the point of view of vocational suitability, and it has been possible to collect much valuable knowledge concerning the effect of psychological reactions on occupational efficiency. The work previously done on accident proneness has led to requests being made for the application of the tests to motor drivers, who are now being

¹ London: H.M. Stationery Office. 1934. (4d.)

submitted to these tests in three large transport companies and in two branches of the Army employing lorry drivers. A study of environmental conditions shows that good lighting has a marked influence on the output even of workers engaged in occupations such as tile-pressing, which make little demand on visual capacity. The effects of noise have been investigated in two groups of weavers over a period of twelve months, and it was found that the performance of the group wearing ear-defenders was appreciably better than that of the control group. Work on the physiology of heating and ventilation includes determinations of the best methods for measuring skin temperature and radiant heat.

SUBCUTANEOUS HAEMOSTASIS IN OPERATIONS

J. Riese,¹ noticing that vessels in the skin and superficial fascia which have been divided in a surgical incision soon cease to bleed if left undisturbed, and that in such a case the healing of the wound is particularly good, recommends that these vessels should not be injured by the customary ligature, suture, or clamping. By such avoidance of tissue trauma he has reduced the percentage incidence of pus formation in the operation wound from 4 to 0.7 per cent. At the same time his proportion of post-operative haematomata increased from 4.5 to 5.5 per cent., but Riese regards haematoma formation as tending to prevent rather than favour infection. Severe bleeding after operation was noted only once in over 2,000 cases treated without artificial subcutaneous haemostasis, and in this instance came from the inferior epigastric artery. With the same purpose of avoiding injury to the tissues, Riese has abandoned the firm bandaging of wounds, and makes minimal use of drainage (except after pleural and thyroid operations). A large haematoma is punctured laterally to the suture line, or if it has opened spontaneously it is emptied and the surfaces at the place of perforation are resewn.

GORDON MEMORIAL COLLEGE, KHARTUM

The latest report of the manifold activities of the Gordon Memorial College at Khartum reflects the great progress made in 1933. Of more special medical interest is the account of the work carried on at the associated Wellcome Tropical Research Laboratories. Facilities granted to the bacteriological section for conducting all the post-mortem examinations in the Khartum Civil Hospital have resulted in further additions of valuable pathological material to the museum, the training potentialities of which have thus been enhanced. It will be recalled that the college is run on secondary school lines, with emphasis on medical and scientific training, and in co-ordination with the local medical curriculum. The museum has now a collection which is fairly representative of most of the tropical and other diseases occurring in the Sudan. The exhibits have been catalogued with descriptive clinical and pathological data, and are proving valuable for the teaching of pathology. Owing to financial stringency the malarial investigations in the Gezira had to be terminated last March. Work already done has established the danger of borrow pits in villages as primary breeding places

of the malaria-carrying mosquito during the rains, and its preference for the sunlit collections of waters in the Abu Isherin and Abu-Sitta canals, and less frequently in the dawrans at later periods of the year. Dissections of adult female mosquitos collected near native habitations showed 2 per cent. infected during the most malarious months. Children up to the age of 12 appear to be the main reservoirs of infection, and represent 75 per cent. of the gametocyte carriers in the district. Another series of tests, continued for a year, showed that there was a seasonal period of a few months for the presence of gametocytes in the blood. This important observation requires checking by future investigations, since it indicates a possible line of control by intensive gametocyte therapy during those few months. Sufficient data have also been collected for the publication of a paper on the epidemiology and endemology of bilharziasis in the Sudan. Ample proof was forthcoming that the canals in Egypt maintain their own constant supply of molluscs, and thus negative the view constantly expressed in the Egyptian press, that the Sudan is responsible for the spread of bilharziasis in Egypt. Berries of the tree *Balanites aegyptica* have been found useful for destroying these molluscs, which are carrier hosts of bilharzia; they can also be employed for the elimination of the water-flea cyclops, which is the carrier of guinea-worm. Other local trees and shrubs probably possess active principles of medicinal or commercial value. Chloramine in a strength of 2.6 parts per million killed bilharzia molluscs in twenty-four hours; a weaker solution of 1.3 parts per million destroyed cyclops in six hours. These dilutions had no effect on mosquito pupae. The College administration was altered during the year to improve the teaching and research from the lowest classes up to the allied Kitchener School of Medicine.

By an Order of the Committee of Privy Council, made after consultation with the Medical Research Council, and with the President of the Royal Society, Professor A. J. Clark, M.D., F.R.S. (Professor of Materia Medica in the University of Edinburgh), and Professor J. C. G. Ledingham, M.D., F.R.S. (Director of the Lister Institute of Preventive Medicine, and Professor of Bacteriology in the University of London), are appointed members of the Medical Research Council in succession to Sir Charles Sherrington, M.D., F.R.S., and Dr. A. J. Arkwright, F.R.S., who retired in rotation on September 30th.

Lord Macmillan of Aberfeldy has been appointed a trustee of the Beit Memorial Fellowships for Medical Research in place of the late Sir James Kingston Fowler. The other trustees are: Sir Alfred Beit, Bt., the Right Hon. W. Ormsby Gore, M.P., the Earl of Onslow, Lord Rayleigh, F.R.S., Dr. Edwin Deller, Principal of the University of London, and Sir John Rose Bradford, Bt., M.D.

The Annual Conference of Representatives of Local Medical and Panel Committees will be held on Thursday, October 18th (and, if necessary, Friday, the 19th), in the Great Hall of the British Medical Association's House, Tavistock Square, London.

¹ Zentralbl. f. Chir., June 9th, 1934, p. 1342.

OPENING OF NEW SESSION: AUTUMN DINNERS

ST. THOMAS'S HOSPITAL

About 150 past and present students of St. Thomas's Hospital and other guests attended the annual dinner at Dorchester Hotel on September 28th. The chair was taken by Dr. W. L. WAINWRIGHT, who, in proposing the health of the hospital and medical school, referred to the changing conditions of medical practice, and to the likelihood that in future no medical man would work as an independent unit, but only as a member of a group. He also commiserated present-day students on the complexity of medical training. When he himself was a student there were only about two textbooks on medicine: what they said was gospel, and what they did not say did not matter to anybody! To-day things were done much better scientifically, but the students did not have such a good time as their predecessors.

Sir ARTHUR STANLEY, treasurer of the hospital, referred to the reconstruction of the out-patient department, which, he said, was proceeding according to plan. Half of it had been completed, and in addition to the dispensary and the hall, the medical examination rooms had been opened during the past few months. The remainder of the work was going forward, and he hoped that by August of next year, or even before then, it would be possible to arrange a formal opening of the whole of the out-patient department, which, instead of being like the old department a disgrace to a modern hospital, would be an object of pride to all associated with St. Thomas's. This work had been made possible by a gift of £20,000 made many years ago by the father of the chairman. By the time it could be used the sum had been more than doubled, and then, the money having been invested in Local Loans, the Government conversion scheme enhanced its value by about 30 per cent., and it was possible to undertake the work without incurring further debt. The reconditioning of the wards was also being carried out, and only two blocks now remained to be done. Another important matter to which attention was being given was the improvement of the accommodation and comfort at College House.

Professor LEONARD S. DUDGEON, dean of the medical school, mentioned that a scheme had been mooted for building a new medical school for St. Thomas's on the other side of the road, together with a new out-patient department, at a cost of something like a million had the work been carried out in its entirety. Fortunately, in his view, the unsettled state of affairs generally had prevented that scheme from maturing, and the school remained where it was, and the improvements to the hospital had been carried out as indicated. St. Thomas's was benefiting from the liaison between the voluntary and municipal hospitals, and had arrangements with the council hospitals at Lambeth and at Wandsworth. Speaking of the losses by death which the school had sustained during the year, Professor Dudgeon referred specially to the death of Sir George Makins and to the memorial that had been installed in his memory. Some criticisms had been made of the bust, but he thought it succeeded in representing Sir George, as they wanted to remember him, exactly as he was in life. After referring to other bereavements and to changes due to more pleasant causes Professor Dudgeon went on to remark that one of the greatest achievements in the medical-school world of London for many years was the co-operation now taking effect between the great medical schools of Guy's, St. Bartholomew's, and St. Thomas's. There now existed an executive committee formed of five members from each school; co-operation on the clinical side was actually taking place between St. Bartholomew's and St. Thomas's, and probably within a year or a little longer Guy's would join in. He concluded by toasting the health of the guests, to which Mr. W. GIRLING BATT, dean of St. Bar-

tholomew's, responded, and remarked that the co-operation between the three medical schools referred to was bound to succeed in view of the personality of their respective deans. The health of the Chairman was proposed by Sir CUTHBERT WALLACE, and the Chairman's brief reply closed a very pleasant evening.

MIDDLESEX HOSPITAL

The annual dinner of the Middlesex Hospital Medical School was held at the Savoy Hotel on October 1st, when Dr. E. A. COCKAYNE presided over a company numbering three hundred. The Chairman gave some account of the rebuilding of the hospital and school. When the past and present students assembled a year ago, he said, the west wing of the building was built and occupied, but the site of the crosspiece and the east wing was a yawning pit surmounted by girders. The girders had now been clothed with stone, and the whole building had been roofed over. The completion of the rebuilding programme was in sight; it was expected to raise the outstanding sum of between £80,000 and £90,000 before the end of the year, the final contracts had been signed, and he hoped that his successor in the chair on the next occasion would be able to announce that the whole of the "new Middlesex" was functioning. A generous gift from Lord Woolavington had made it possible to proceed with the paying patients' block, for the accommodation of people unable to meet the heavy costs of a private nursing home and too well off to occupy fittingly the beds dedicated to the poor. This paying block was opened early in the present year, and had proved an unqualified success. Last year Mr. Collins had given the large sum of £30,000 for an x-ray diagnostic department. Plans for this new department had been carefully drawn up, and he believed that in equipment it would be second to none in this country, or perhaps the world. Then Mr. S. A. COURTAULD, who had been one of the great benefactors of Middlesex in the past, had crowned his long series of gifts by one of £15,000 for fitting up the first portion of the crosspiece of the new hospital as a unit for clinical research. This would be a new departure in hospital practice, and he believed that Middlesex would lead a way along which many others would follow. Here the professors of biochemistry and pathology would keep in close touch with members of the honorary staff. Another generous gift was that of Mr. MEYERSTEIN, who had given over £30,000 for the provision of a unit or department of x-ray therapy, to complement the diagnostic unit. The new clinical theatre, which would be of the greatest value to the school, would be completed early in the new year; the department of x-ray diagnosis would be ready by February or March, and the department of x-ray therapy before the summer.

Mr. S. A. COURTAULD, chairman of the school council, spoke of the admirable character of the lay-out in the paying patients' block. Two near relatives of his own had been patients, and had told him how delighted they were with what was provided. With regard to the research unit, for which he himself was partly responsible, the conception was not his own, but it appealed strongly to him because it would bring the actual personnel of the scientific staff of the medical school almost to the bedside of the patient. The clinic ought to be in operation this side of Christmas.

Dr. H. E. A. BOLDERO, dean of the school, said that the numbers entering were almost an embarrassment, and many would-be students had had to be disappointed this year. He added some further details about the clinical research unit, which would give Professors McIntosh, Dodds, and Wright a share in the treatment of certain patients, directly in co-operation with, and equal in

responsibility to, the staff of the hospital. The unit was laid out in six smallish wards, of a size that would be considered luxurious for one, comfortable for two, perhaps a little crowded for three, and it was thought that six such wards would allow of adaptation to future developments. The new clinical lecture theatre would have accommodation for 100, or, at a push, 120. He mentioned that more than fifty old Middlesex men had this year attended a refresher course.

A further response to the toast was made by Mr. P. H. NEWMAN, senior Broderip scholar; after which Mr. A. E. WEBB-JOHNSON proposed the health of the many guests, who included the mayors of Marylebone and St. Pancras, the Regius Professors of Oxford and Cambridge, and representatives of London University, of various medical services, and of the Press. Sir FARQUHAR BUZZARD made a brief reply in humorous vein, and the health of the Chairman was proposed by Dr. R. A. YOUNG.

CHARING CROSS HOSPITAL MEDICAL SCHOOL

The annual dinner of the Charing Cross Hospital Medical School was held at the Café Royal on September 29th, when Mr. J. BRIGHT BANISTER was in the chair. A pleasant informality of proceedings was observed throughout the evening, the absence of an official toast list, by the forethought of the dean, facilitating the digestion of an excellent dinner.

Mr. Bright Banister briefly recorded the events of the medical school during the past year. They had had the misfortune, he said, to lose two valued members of the staff in Dr. E. D. Macnamara and Dr. C. W. Hutt, whose death they deeply deplored. The ophthalmological department had been revived by the appointment to the staff of Mr. Montague Hine. Charing Cross has spread its fame abroad, for Dr. Gordon Holmes was at present lecturing in Canada, and Dr. Hickling had been on an educative mission to New York. Mr. Banister reminded his audience that this was the centenary year of the hospital, and to celebrate this the medical school had acquired a coat of arms. Mr. ERIC CROOK, the dean, said that he thought a big toast list prevented people from renewing old friendships, which was one of the chief reasons for holding an annual hospital dinner. After Mr. NORMAN LAKE had described the coat of arms in terms of gules and bezants, Dr. WATTS EDEN, Mr. CHARLES GIBBS, Dr. WILLIAM HUNTER, and Dr. DAVID FORSYTH were prevailed upon by a minority opposition to the "no speeches" decision to make a few remarks.

The reunion, so well begun, was continued into the early hours of the morning at the medical school, where dancing was in progress.

UNIVERSITY OF LONDON MEDICAL GRADUATES SOCIETY

The autumn extra-metropolitan dinner was held on September 28th at Queens' College, Cambridge, by kind permission of the President and Fellows of the College. The president of the society, Mr. W. MCADAM ECCLES, occupied the chair, and among others present were the President of Queens' and Mrs. Venn; the President of the Royal Society, Sir Gowland Hopkins; Sir Leonard Rogers, K.C.S.I.; Lady Barrett, Sir Charlton and Lady Briscoe, Dr. Vincent Dickinson, Dr. Dorothy Hare, Dr. Drummond Robinson, Dr. Kenneth Soltau, Miss Ida Mann, Dr. Harold Pritchard, and Mr. Musgrave Woodman.

The society, which was founded in 1928, has now 548 members, of whom fifty-four are over-seas. Mr. Eccles thought that the fact of a life subscription of only £1 was a distinct attraction. He hoped that members would

induce other medical graduates to join at an early date. He further said that in the world tour which he hoped to make next year in connexion with the British Medical Association Meeting in Melbourne he intended to try to see every medical graduate of the University of London at each of the ports at which he called.

In proposing the toast of "The Guests," Mr. McAdam Eccles alluded to the great honour which had recently been conferred on Sir Gowland Hopkins—that of the Albert Medal of the Royal Society of Arts, thus linking the name of the "President of the Royal Society" with such illustrious names as those of Faraday, Kelvin, Lister, Rayleigh, and Rutherford. Sir GOWLAND HOPKINS, in a very apt reply, pointed out that the laboratory worker should not be looked upon as one divorced from the clinician, and that as it was difficult in the ward to carry out control experiments the laboratory was of real value. All present enjoyed the sound sense coupled with the humour of his speech. The President of the society, in proposing the health of the President of Queens' College and Mrs. Venn, referred to the long and close connexion of the family of Dr. J. A. Venn with Cambridge and Queens', no fewer than three members having been Fellows of that College, and one a Fellow of Caius. Dr. VENN, in reply, pointed out that any one college having distinction in being associated more with one faculty than another was dying out, and that Queens' now had quite its share of medical graduates. A very pleasant evening closed by many present having the privilege of seeing the beautiful gallery in the President's lodge.

All communications relating to the society should be addressed to the honorary secretaries, U.L.M.G. Society, at 11, Chandos Street, Cavendish Square, W.1.

ST. MARY'S HOSPITAL MEDICAL SCHOOL

The annual dinner of the past and present students of St. Mary's Hospital was held on September 29th in the library of the new medical school, with Dr. P. MONTAGUE SMITH, senior physician to the Princess Louise Kensington Hospital for Children, in the chair. Previous dinners had been held in restaurants, and the less formal and more intimate atmosphere of the function this year was warmly welcomed and reflected in the speeches. It was agreed that it was desirable to hold future dinners in the medical school.

After the loyal toasts Mr. DUNCAN FITZWILLIAMS, senior surgeon to the hospital, proposed the health of the Chairman in a racy biographical speech, which combined familiarity with esteem. In his reply Dr. MONTAGUE SMITH extended a welcome to the guests, who included the Vice-Chancellor of the University of London and the Mayor of Paddington, and recalled the names and fame of past celebrities of St. Mary's. He passed to an appreciation of more recent outstanding members and benefactors of the hospital, paying a warm tribute to the great services of Dr. C. M. Wilson, dean of the medical school, whose name he coupled with the toast of "Prosperity to the School." Dr. Wilson, responding, referred to the triumph of endeavour, which had been crowned when the King last autumn had opened the new medical school. He described how, since the war, increasing efforts had been made to secure that the entry to the medical school should become more and more selective, while the advantages to students, rendered possible by the rebuilding operations, should be intensified. Referring to the athletic triumphs of the previous year, including the winning of the two Rugby and two cricket cups, he concluded with a comment on the value of athletic achievement in the medical curriculum.

After the dinner visits were paid to the large swimming bath beneath the library, the squash court, and other parts of the premises. It was thus shown that a great amount of recreational facilities could be enjoyed by the students and resident medical staff of St. Mary's without leaving the precincts of the hospital.

CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS

The sixth annual dinner of the Chartered Society of Massage and Medical Gymnastics was held at the Café Royal, London, on September 26th, when Mr. R. C. ELMSLIE presided over a very large attendance of members and guests.

Dr. A. H. DOUTHWAITE, in proposing the health of the Chartered Society, said that in its earlier years it was, though enthusiastic, small, and received very little support from outside. The war brought about an appreciation of the value of massage, the demand for masseurs and masseuses increased, and with it the supply, perhaps in excess of the demand. By 1920 the society had a membership of 3,000; it then amalgamated with the Manchester society, and at the present time its membership stood at 9,000. The medical profession, said Dr. Douthwaite, had not always recognized the value of the masseur and the masseuse in helping to restore patients to health, and one of the indirect results of what might be termed "the apathy of the medical profession in this matter" was that the osteopath and similar practitioners had flourished exceedingly. The position was now fast improving, and, thanks to the growing appreciation of the medical profession, there was an increasing demand for the services of the members of the society. In large measure the change was due to the president, Mr. Elmslie, who had worked with astonishing enthusiasm in its interests.

Mr. R. C. ELMSLIE, in responding, said that it was now becoming the custom for medical practitioners to have a list of names of members of the society whom they were ready to recommend to such of their patients as needed this service. A reference had been made at the dinner the previous year to the fact that, in conjunction with the British Medical Association, steps were being taken to form a register of all engaged in this class of work. Further discussion had shown that in order to establish such a register there must be powers to insist upon certain qualifications, and to remove names from the register following upon misbehaviour. A legal basis was therefore necessary, and with this object a memorandum and articles of association had been drawn up and submitted to the Board of Trade. The Board of Trade, however, had turned the scheme down, and had suggested that an attempt should be made to proceed without such legal authority and see what could be achieved. In their own view that was of no use; there must be legal authority if the scheme was to be made effective alike in the interests of the members of the society, the medical profession, and the public. It was essential that all who did this work should be fully qualified and certificated, and he was glad to hear from the Medical Secretary of the British Medical Association that the suggestion of the Board of Trade was not to be the end of the matter, and that further steps would be taken. The Chairman then referred to certain events of the year.

The toast "The Guests" was proposed by Miss S. GRAFTON, and in the course of his response Sir HOLBURN WARING, President of the Royal College of Surgeons of England, commented on the efforts that had been made to obtain a charter which would bring in other branches of treatment and embrace radiographers and others. This, he said, was a thorny subject. There were those who were desirous of obtaining a special Act of Parliament which would enable a registering body to be set up, with powers of examination, licensing, and discipline, but it appeared to him that the best course to pursue was to approach the General Medical Council and see whether some general legislation could be obtained which would bring in the ancillary branches under one control, the primary authority being exercised by the General Medical Council. Mrs. GILMOUR REID, president of the Australasian Massage Association, who also responded, spoke of the difficulties with regard to registration in Australia. Registration existed in South Australia and Victoria, but not in New South Wales. A registration scheme for the whole of Australia would result in a great improvement of the position.

Nota et Vetera

THE PICTURE OF HENRY VIII PRESENTING THE ACT OF UNION TO THE BARBERS AND SURGEONS IN THE POSSESSION OF THE ROYAL COLLEGE OF SURGEONS

The story of the picture of King Henry VIII presenting the Act of Union to the Barbers and Surgeons now in the collection at the Royal College of Surgeons of England, and how it came into possession of the Company of Surgeons in 1786, is one of interest, and is not perhaps generally known.

The account of its acquisition by the Company is thus recorded in the minutes of the Court on July 6th, 1786.

"The Master informed the Court that in a sale of pictures by Monsieur Desenfans, a large capital picture was exposed to sale being a cartoon painted by Hans Holbein representing King Henry VIII delivering the Charter to the Barber-Surgeons in the year 1535 and having examined the same and being satisfied of its undoubted authenticity and that it was the original picture of that subject, and Mr. Grindall having also examined it and being of the same opinion, and thinking such an opportunity of procuring the possession of such a picture should not be missed and being of opinion that the same might be procured for a reasonable price, they had treated for the purchase and having reduced the terms to fifty guineas they had purchased the same on the account and for the use of the Company, and the Court of Examiners had issued the price of it out of the Company's cash."

A later minute records: "Resolved, that the Court doth highly approve of the conduct of the Master and Mr. Grindall upon this occasion and returns them thanks for their attention to the concerns of the Company."

Soon after the picture was purchased the Company decided to have it cleaned and restored, and a Mr. Lloyd was engaged to carry out the work. He demanded £400, but was eventually beaten down to fifty guineas.

When the College of Surgeons was formed the picture was removed to the new building in Lincoln's Inn Fields in 1806, where it still remains part of the fine collection of pictures in the possession of the College. Some twenty years later William Clift, the Conservator of the Museum, being dissatisfied with its condition, decided to attempt to clean it himself, and in so doing discovered to the right of the background a casement with a view beyond it of a steeple, an embattled tower, and the roofs of gabled houses. He thought that the steeple was that of St. Bride's, Fleet Street, but a further examination revealed two steeples as well as the tower, and it was suggested that the taller of the two could be no other than the old wooden steeple of Old St. Paul's, which was struck by lightning and burnt down in 1561. If this be the case the view seen through the casement must have been painted before that date.

The Rev. E. G. O'Donoghue, who examined the picture in 1918, was of the opinion that the steeple was that of Old St. Paul's and the square tower St. Augustine's, which stood to the east of the cathedral at the junction of Old Change and Watling Street.

The building in which the ceremony took place was originally thought to be Bridewell, but it has been pointed out that the palace was not begun until 1522, and it was scarcely habitable in 1540. King Henry rarely visited it after 1529, and it is therefore probable that Baynard's Castle, which was used as a Royal Palace at the time, may have been the scene of the ceremony. According to Dr. Ganz, it is "the same chamber with the same hangings, probably the throne room at Whitehall as in a large picture at Hampton Court. It is possible that the King may have sat for the picture at Whitehall, and that Holbein made use of the surroundings at his hand, but the view from the

window seems to indicate that the room represented was in Bridewell."

It is in the window and other details that the picture in the possession of the Royal College of Surgeons differs from that still hanging at Barbers' Hall in Monkwell Street, attributed to Holbein. For a long period the latter picture was supposed to represent the granting of the Charter by the King to the Barber-Surgeons, but Mr. Sydney Young has shown this to be incorrect. In his opinion the picture exhibits a Charter with the Great Seal pendant. He points out that the King was but 21 years of age in 1512 and was 49 in 1540, which latter age accords with the picture. Moreover, Vicary, Ayleff, Harman, and the others represented, were members of the Court in the latter year, but not in 1512.

Vicary, who is depicted as receiving the instrument, was Master from September, 1541, to September, 1542. There is every probability that the painting was executed during his term of office, and that is why Holbein paid him the compliment of putting him in the chief position in the picture. These considerations are sufficient to demolish the Charter theory, and point to the hypothesis that it is the Union of the Barbers' Company with the Guild of Surgeons, accomplished by Act of Parliament in 1540, which is commemorated. "The King is represented as being about 50, and on the left are Dr. John Chambre, Dr. Butts, and behind him Thomas Alsop, the Royal Apothecary. The tablet on the wall with its inscription is said to be of a later date than Holbein's work, and is said to have painted over a window." The following is a translation of the Latin inscription:

"To Henry the Eighth, the best and greatest King of England, France, and Scotland. Defender of the Faith and next to Christ supreme head of the Church of England and Ireland, the Company of Surgeons dedicate these with their united prayers.

A grievous plague had ravaged the region of England,
Afflicting man's spirits and penetrating his frame,
God, pitying from on high this remarkable scourge
Commanded thee to perform the office of a good physician.

The light of the Gospel flies around on glowing wings,
This will be the balm to enfeeble minds;
Whilst the disciples of Galen meet to raise a monument to thee,
And all disease is swiftly dispelled by thy power.

We therefore, a suppliant band of thy physicians,
Solemnly dedicate this house to thee,
And mindful of the favour with which thou, O Henry,
hast blessed us,
Invoke the greatest blessings on thy rule."

Mr. R. H. Wornum, who was keeper of the National Pictures in the first half of the last century, states in his *Account of Life and Work of Hans Holbein*, 1867, that "the picture in possession of the Company of Barber-Surgeons was probably painted about 1541, and Holbein may have died before it was completed." He asserts that some parts were repainted and never touched by Holbein. We know from the references in Pepys's Diary that it was damaged in the Great Fire of London in 1666, for he tells us that when he saw it in 1662 he greatly admired it. Then in August 29th, 1668, he wrote:

"At noon comes by appointment Harris to dine with me and after dinner he and I to Chirurgeons' Hall where they are building it new, very fine, and there to see their theatre which stood all the fire, and which was our business, their great picture of Holbein's thinking to have bought it by the help of Mr. Pierce for a little money. I did think to give £200 for it, it being said to be worth £1,000, but it is so spoiled that I have no mind to it and is not a pleasant though a good picture."

Wornum suggests that after it was thus damaged it underwent restoration, and that the tablet on the wall with the inscription was introduced in place of the

original window still to be seen in the picture at the Royal College of Surgeons. Mr. Arthur B. Chamberlain, in his life of *Hans Holbein the Younger*, 1913, says that "the original background was the window" and that the large white tablet on the wall to the right which helps to spoil the general effect was a late addition. To return to the picture at the Royal College of Surgeons, the early history of which is obscure, he states:

"On January 13, 1618, James I wrote from Newmarket to the Company of Barber-Surgeons asking that their picture should be lent to him as he was anxious to have a copy made of it, and promising that this should be done expeditiously and the original redelivered safely. The copy then made is in all probability the one now in possession of the Royal College of Surgeons, which is smaller than the original, and an indifferent version of it on paper attached to canvas. The figure of Alsop is omitted and in place of the tablet with inscription is the window with a view of the church tower, proving that if it is not the copy ordered by James I, it is at least a very early version of it."

Sir D'Arcy Power, who had an opportunity of closely examining this picture a short time ago, says:

"The back row of figures on the left of the King are evidently by an inferior artist than those of the picture at Barbers' Hall, some of the heads being quite grotesque and more like caricatures than the faithful portraits of Holbein. It is painted upon four pieces of paper, which are joined together upon a canvas to form the picture."

The early history of the painting is still obscure, and if it is the copy made for James I we have been unable to trace it in the Royal Collections of the seventeenth century. Mr. C. H. Collins Baker, the late Surveyor of the King's pictures, has kindly made a search among the catalogues of the Royal Collections and finds that the picture did not pass into the collection of Charles I, nor does it occur in the list of his pictures sold by the Commonwealth. It is not included in the catalogue of the pictures in the time of Queen Anne, and it may therefore be assumed that it was disposed of privately, and eventually came into the possession of M. Noel Desenfans about the middle of the eighteenth century. Desenfans, whose name is linked with Dulwich Gallery, was Consul-General of Poland in Great Britain at this period. He was a well-known connoisseur and art collector, and bought many pictures to form a collection for the King of Poland. His own pictures were offered for sale in 1786, and the picture of Henry VIII and the Barber-Surgeons, now in the possession of the Royal College of Surgeons, was among them and purchased for the Company of Surgeons. If, as surmised, this picture is the copy of the original made for James I, it is especially interesting as showing the background of the Holbein at the Barbers' Hall in its original state. The Holbein picture is painted on panel and measures 10 ft. 3 in. by 6 ft., while the copy in the collection at the Royal College of Surgeons is 9 ft. 2 in. by 5 ft. 2 in. The former was engraved by Bernard Baron in 1736.

C. J. S. THOMPSON, M.B.E.,

Hon. Curator, Historical Collection of the
Royal College of Surgeons of England.

The *Klinische Wochenschrift* of September 15th is a special number with a semi-political significance. The nineteen articles which it contains are written by physicians and surgeons of the Saar area. In a preliminary note Dr. H. Dietlen, on behalf of the Saar practitioners, describes the contents as a contribution made in honour of the ninety-third meeting of the Society of German Scientists and Physicians by German doctors in the Saar who wish to express their unity—never lost in the spirit—with their colleagues in the Reich, and their gratitude for the participation of their German colleagues, during the separation, in the proceedings of scientific and medical bodies in the Saar.

Scotland

National Health Insurance Conference

The twenty-second annual Conference of the Scottish Association of Insurance Committees, held at Stranraer on September 28th and 29th, was attended by about 200 delegates from all parts of Scotland. After a civic welcome by Provost Murray of Stranraer, Mr. John Riddet, the president, in his address said that the British national health insurance scheme was a model to the world, but it must cause united concern to them in regard to the improvement of the services. The medical service was much better than it was when the scheme was instituted. In its scope, however, it was a general practitioner service, and it was desirable that it should be amplified by consultant, specialist, laboratory, and diagnostic aids, and that insured patients should have such institutional and nursing facilities as might be required. The clamant need of dependants for similar benefits was also generally recognized. Financial stringency at the moment appeared to hinder any great development, but they must continue to press for a full and complete medical service in the hope that the means would ultimately be found. The Conference unanimously resolved that the Government be urged to promote legislation to include within the scope of national health insurance young persons entering employment between the ages of 14 and 16. A resolution was also unanimously passed that, in the opinion of the Conference, the right to medical benefit lost by insured persons under the provisions of the Act of 1932 should be restored as soon as possible. It was remitted to the Executive Committee to consider how uniformity could be obtained as between insurance committees in Scotland in regard to making proprietary medicines available to insured persons; it was suggested that details should be discussed with the British Medical Association and the Pharmaceutical Society. Mr. A. B. Gilmour, reporting on the work of the Drug Accounts Committee, referred to a number of unusual and unsuitable prescriptions which had passed through his department. He suggested that in the matter of vitamins care should be taken to see that what could be provided from the kitchen was not provided from the drug fund. There had been some laxity and luxury in prescribing—for example, a proprietary brand of orange squash, a tin of health salts for a child of 3, a dozen safety razor blades, etc. One insured person, in the course of nine years, had received 8 cwt. of an ointment containing boric acid at a cost of £117, and was still receiving treatment. Dr. Kerr, Edinburgh, moved a resolution that unrestricted freedom of change of doctor should be restored to insured persons; this was unanimously approved.

At the meeting on September 29th Mr. John G. Highton, Secretary of the Department of Health for Scotland, in an address on the subject of a national health service, said that not nearly enough had been done in the past to resist the onset of disease, and it was along these lines that a great field of opportunity lay. Referring to the remarkable advances in public health measures in a comparatively brief period, he said that a medical officer of health had not been appointed for Glasgow until after 1860, and five and ten years respectively had elapsed before a fever hospital had been opened and a sanitary inspector appointed. Towards the end of the nineteenth century there had been a great development of health services, but there was no public provision, except in regard to infectious diseases, for medical and surgical treatment in the homes. In the year 1881 there were 9,000 families in the Bridgeton division of Glasgow, of

which only 882 had more than two rooms, and the death rate was 30 per 1,000. The quadrangles of the houses, which were a pleasant feature on the Continent, had an evil significance in Scotland, containing in their centres a privy midden. In school medical inspection there was not yet a complete system of co-ordination with the home, and there was a lack of co-ordination between the home and industry. Much still required to be done in linking up health measures with domiciliary treatment by the general practitioners. Some of the problems which our health service still solved only partially were those dealing with nutrition, environment, and open spaces for the physical development of the body and refreshment of the mind. Referring to a recent tour he had made of various housing operations in Germany, Holland, Austria, and France, the speaker said that he had been most impressed by the good environmental conditions of the working classes; there were gardens immediately opposite the houses, and not miles away in public parks, while every house he visited was very clean. Cleanliness was to a large extent alien in Scottish practice, but he thought this was largely an educational matter. Sir Henry S. Keith, in proposing a vote of thanks to Mr. Highton, said that personal considerations of health did not get all the attention they deserved—for example, in regard to the fever hospital of his town, it was a remarkable fact that at least 50 per cent. of the patients admitted were verminous. There was no reason nowadays why any child or adult should appear in hospital in a verminous condition. He thought that they were not sufficiently impressing upon the individual and the family the necessity of doing something themselves in the direction of health.

Edinburgh Public Medical Service

The proposal for a public medical service in Edinburgh was outlined in the *British Medical Journal* of June 30th last. The scheme has now been adopted, and about one hundred general practitioners in the city have joined it. The arrangements of the scheme follow the lines of the model scheme issued by the British Medical Association, and the area of the service is to be the city of Edinburgh. The first meeting of the practitioners who have joined the service was held on September 18th, in the British Medical Association House, Edinburgh, when Dr. F. K. Kerr was appointed chairman, Dr. A. F. Wilkie Millar honorary treasurer, and Dr. A. P. Robb honorary secretary. An office has been secured at 13, Heriot Row, Edinburgh, where Mr. R. Pairman Miller will act as general secretary. The subscriptions payable by members have been fixed at 4d. per week for one dependant, 8d. for two, 10d. for three, and 1s. for four or more (including medicines), and these will be gathered by collectors weekly or monthly. Canvassing is prohibited, and persons wishing to join the service must do so through their own doctor. There is free choice of doctor and chemist, as under the national health insurance scheme. Membership is limited to dependants of insured persons and others with incomes up to £250 per annum. The scheme has met with the approval of the Edinburgh Insurance Committee.

The Undesirable Tenant

A paper which Dr. A. K. Chalmers read before the Royal Philosophical Society of Glasgow, together with additional notes relating thereto by Sir John Mann, has been published by the Housing Committee of the Corporation of that city as a pamphlet under the title "Can the Undesirable Tenant be trained in Citizenship?" The authors review the progress of slum clearance and the progressive steps that have been taken to place upon local authorities the responsibility for rehousing, and indicate

the extent to which these responsibilities have been carried into actual effect, especially in Glasgow; but, as their title indicates, they are chiefly concerned with the problem which emerges from these activities—namely, what is to be done as regards that section of the displaced slum dwellers who do not respond in a satisfactorily social way to the opportunity for improvement which is afforded them? The first point is to discover the extent of this problem; what proportion of the population concerned are found to be quite “undesirable” or “incorrigible” tenants so that they constitute a “refractory group”? Here we have to deal with two sections: those affected by the clearance scheme who refuse to accept the alternative houses provided for them, and those who do accept but nevertheless fail to prove socially satisfactory in their new environment. It appears that experience indicates that some 20 to 25 per cent. of the displaced population will fall within the former class. Not all of these, however, are necessarily incorrigible. A number of them will be reasonably good tenants or lodgers who are able to provide for themselves by other means. Of those who are rehoused under such schemes it seems that about one-tenth soon prove to be undesirable tenants. It may thus be assumed that the statement commonly made that about one-quarter of present slum dwellers prove to be “slum-minded,” and so difficult to rehouse with good results, is approximately correct. Three ways of dealing with this residue are mentioned in the pamphlet. Clearly they ought not to be abandoned and removed from such educational influences as can be brought to bear upon them. Some schemes, especially in Holland, have placed them—under certain regulations for promoting cleanliness, respectable living, and punctual payment of rent—in a special simplified type of house or building isolated from the rest. Others provide such a simplified form of house, not in isolation, but intermingled with blocks of the normal type. In spite of the apparent success which has so far attended some such arrangements the objections to this method are obvious and important, especially as they affect the children in families so housed. It is probable that many social workers will agree with Dr. Chalmers that in most cases it is better to rely upon a continued educative supervision under a rehousing scheme of normal character, especially by selected and trained women managers and supervisors according to the methods initiated by Miss Octavia Hill. This, together with the continuance of the beneficial influence shown to be exerted by maternity and child welfare centres, by the school medical service, and by the elementary school, should, within a generation or two, reduce the problem to much smaller dimensions, and reveal whatever residue there may be in whom inherent and inherited traits resist the effects of improved environment.

Housing in Edinburgh

At a meeting of Edinburgh Town Council on September 27th a scheme for assisting in the erection, by private enterprise, of new houses for the working classes was considered. It had been estimated that 750 houses would be erected during the year from May, 1934, to May, 1935, and it was reported that 310 houses had already been completed and occupied. It is now proposed that the corporation should advance money directly to builders who erect houses for letting purposes, on the same terms and conditions as to building societies, while the rate of interest to be charged is to be that fixed by the Secretary for Scotland under the Small Dwellings Act of 1899. It was also agreed, on the recommendation of the Public Health Committee, that an endeavour should be made by the corporation to erect 250 additional houses to replace existing unfit ones during each year of the five-year housing programme, 1934-8. It was pointed out that

the corporation was still waiting for the Government's proposal regarding overcrowding before dealing with the question of building suburban bungalows, which would be far removed from working centres, and rehousing dispossessed slum-dwellers in new tenement houses erected upon central derelict areas.

England and Wales

Water Supplies and the Drought

The water situation of the country was further reviewed at a meeting of the Water Supplies Emergency Conference held at the Ministry of Health last week. The rainfall in August and the early part of September has improved supplies in a number of areas, but economy in consumption is still needed. Of 225 large water undertakings, 202 have reported no serious shortage, present or prospective, sixteen report present shortage in their supplies, and seven not at present suffering from shortage report that the position may worsen later, though measures have been prepared for dealing with the situation. Of 745 urban authorities with populations under 20,000, 705 have reported no serious shortage of water, present or prospective, thirty-two report serious shortage, and eight whose areas are not at present suffering from shortage fear it later if enough rain has not fallen by the end of September. Of 536 rural district councils 339 have reported no serious shortage, present or prospective, 156 report serious shortage now in some part or parts of their districts, and forty-eight report that they are not yet suffering from shortage, but may suffer later. Engineering inspectors of the Ministry continue to make special visits to districts where the position calls for investigation. A large number of schemes of permanent improvement of supplies are being carried out or are being prepared. So far forty-one applications have been received under the Water Shortage Act for special emergency powers, about half of which are for new sources of supply, and new powers have already been given in twenty-six cases. Applications for grant under the Rural Water Supplies Act have been received for schemes of permanent improvement at an estimated total cost of £2,900,000. Grant has already been promised to ninety-seven councils, covering 604 parishes, for schemes estimated to cost £1,650,000. The Metropolitan Water Board reports that rainfall in August and early September made it possible to abstract more water from the river and to increase the amount in storage. Reserves had, however, to be drawn on during the third week of September, and economy is still needed. The general rainfall over England and Wales during August was 3.18 in., compared with a normal fall of 3.35 in. Generally the deficiency during the four months ending in August was 26 per cent. Rainfall during the first three weeks of September was less than the normal in most areas, though in others there was an excess locally due to severe thunderstorms.

Paying Patients' Block at Guy's

The foundation stone of Nuffield House, the new building for paying patients at Guy's Hospital, was laid on October 3rd by Lord Nuffield, who in December 1st offered the governors of the hospital £45,000 for that purpose. Fifty years ago—in September, 1884—Guy's opened a ward for private paying patients, the first ward of the kind to be instituted in a general hospital. At first it contained twelve cubicles. Later the number was increased to twenty-three, and a resident medical officer

appointed to look after it. To-day thirty cubicles and one room are available for private patients, but the demand is so great that cases have to wait two or three weeks before they can be admitted. The new paying patients' block will accommodate seventy-three patients. Plans have been prepared, and have received the approval of the Court of Governors and of King Edward's Hospital Fund for London.

The block will contain fifty-three separate rooms and five four-bedded rooms, wherein each patient will have a cubicle space. It will have its own sister-in-charge, resident surgeon, and fully equipped operating theatre suite. There will be waiting and lounge rooms for visitors and patients, and a complete kitchen and food unit. Each of these units will be in direct service to all floors by duplicated electric lifts. Special accommodation is allocated for radiology. A feature of the building is the roof garden. The whole of the roof, approached by electric bed lifts, will be available for patients, and the central portion is to be enclosed with movable glass slides. After the ceremony of the stone-laying, Lord Nuffield presented prizes to the students of the Medical School.

British Spas Federation

The bi-annual meeting of the British Spas Federation was held at Leamington last week. Among the numerous matters discussed was the question of the recognition by the Government of the proved value of the British spas and its appreciation of the spas as an asset of national importance, as is the case on the Continent, where, incidentally, a number of the spas are State-owned and controlled. The adoption of a system of diets was also discussed. One or two of the spas have recently instituted an elaborate dieting scheme, and the remaining spas in the Federation are to consider the adoption of similar methods. The Federation, in conjunction with the British Medical Association, has completed a comprehensive training scheme for all candidates for posts as spa attendants. This scheme is to be adopted at once, and will ensure that all new members of spa staffs will be thoroughly conversant with the theory and practice of spa work. A few of the larger British spas have already training schemes in operation, and no one is allowed to give treatment to a patient there unless he or she has the necessary training and certificates, but the remaining spas will now adopt this stringent course.

Housing Policy

On October 1st the Minister of Health, Sir Hilton Young, started a tour of large towns in connexion with the housing policy of the Government. The object of the tour is to explain to the housing authorities the Government's proposals for dealing with the evil of overcrowding, and to enlist their interest in the work. The Minister will also take the opportunity of discussing with the housing authorities the work of slum clearance, and other interests of local government. The towns to be visited are: Plymouth, Birmingham, Sheffield, Wolverhampton, Stoke, Manchester, Liverpool, Rochdale, Norwich, and Bradford; and the tour, which will occupy the greater part of October, has been designed to cover the widest possible area and variety of housing conditions.

The Health and Cleanliness Council (5, Tavistock Square W.C.1) has recently produced a new poster in colours, "Health Insurance." Specimens of this poster will be sent to those interested by the secretary, Miss Norah March, and the council is prepared to consider supplying copies in bulk, free of charge, where these would be of substantial assistance to health education.

CORRESPONDENCE

R.M.B.F. Christmas Gifts

SIR,—It has been my privilege for many years to appeal to your readers for contributions to enable the Royal Medical Benevolent Fund to distribute Christmas gifts. I desire to express my personal gratitude to my many medical colleagues who have so generously responded to the appeal in recent years, and especially to the medical societies and Panel Committees who, together with Branches and Divisions of the British Medical Association, have arranged collections at their meetings in aid of this particular need.

It is impossible to give any details in a short letter of the sorrowful lives of those we endeavour to help; in a great many cases tragedy has befallen them. It may not be realized that in issuing this appeal I write on behalf of over 650 beneficiaries, for that is the number on our books, and I feel, therefore, a great personal responsibility as to whether my appeal will suffice to persuade your readers of the urgent need of a generous response.

One medical practitioner, a married man, wrote recently to the Fund that at the age of 66 he had suffered a complete breakdown in health and further work was out of the question. He had done all that was possible to keep going, and was still not in debt, as he had drawn on his endowment policies. But he had now come to the end of his resources, and had been forced to take his little girl, aged 14, away from school, as he could not meet the next term's fees, his income being £60 per annum.

The Fund is now helping this colleague with a yearly maintenance grant, but we want at Christmas to give him and many others the unlooked-for Christmas gift. We try to distribute 30s. to each. I ask your readers to help us to do so. Donations will be gratefully acknowledged by the honorary treasurer, Royal Medical Benevolent Fund, 11, Chandos Street, London, W.1.—I am, etc.,

September 30th.

THOS. BARLOW,
President.

The Eichholz Clinic

SIR,—May I beg the hospitality of your columns to invite members of the medical profession to visit the Alfred Eichholz Memorial Clinic, which was opened in July by the Prince of Wales? It is unique among clinics, inasmuch as it is staffed by blind masseurs and masseuses, whose very blindness appears to be an aid rather than a disability in the development of tactile sensibility. There are sighted medical supervisors and fully qualified sighted sisters, and the very complete equipment for electrotherapy has been specially designed for the use of blind operators. Apart from its interest as a useful service to the medical profession, it has claims on all who would like to encourage a body of men and women whose otherwise sombre lives are being brightened by the opportunity of doing really useful work. The clinic is lodged at 204, Great Portland Street, W.1.—I am, etc.,

London, W.1, Oct. 1st.

MOYNIHAN,
Chairman of the Medical
Advisory Board.

Muco-purulent Tubo-tympanic Infections

SIR,—I was interested to read in your issue of September 22nd (p. 544) Dr. T. Ritchie Rodger's lucid and concise presentation of the above subject. It is a type of infection which at times gives one considerable trouble.

The advisability of searching for, and thoroughly eradicating, any source of infection in the nose or its

adnexa is clearly expressed by him, and is a "dictum" with which I am in thorough agreement. It is surprising how frequently an unsuspected, almost occult, nasal sinus infection, generally of the mucoid variety, is found, particularly in the maxillary sinus, in cases of catarrhal middle-ear deafness. Mere inspection of the nasal passages often fails to reveal this mild sinus infection. Transillumination and x-ray examination give some assistance, but in my opinion nothing short of puncture and aspiration of the maxillary sinus, in every doubtful case, completes the examination.

Subacute catarrhal middle-ear deafness which has proved resistant to other simpler remedies is often quickly relieved when the offending nasal sinusitis is discovered and treated. The earlier the nasal sinusitis is treated the better the prognosis, for there is a tendency, as I have shown elsewhere,¹ for the serous and mucoid exudation in the middle ear to become more and more fibrinous and difficult to evacuate as time progresses. Dr. Ritchie Rodger mentions the value of early evacuation of a serous or mucoid exudation in the middle ear by a paracentesis tympani and immediate inflation per the Eustachian catheter. It is a form of treatment which, following the practice of the late Sir William Milligan, I have adopted for many years with good results.

I feel convinced, however, that if natural resolution of the otitic exudation does not follow quickly other simpler remedies, the sooner it is evacuated the better the result. Paracentesis may have to be performed on more than one occasion, since there is a tendency for the incision to heal before the catarrhal condition in the Eustachian tube and middle ear has completely resolved.

Unlike Dr. Rodger, I rarely prescribe any astringent or solvent drops for use after the paracentesis, for fear of inducing a secondary infection. The external auditory canal is first thoroughly cleansed by syringing with carbolic lotion (1 in 80), paracentesis performed under a local anaesthetic, and the middle ear then inflated by means of the Eustachian catheter. Unless the fluid evacuated is copious I do not dry out the external canal. A pledget of cotton-wool is placed in the external meatus and the patient warned to reapply the wool should it become soiled, but on no account to leave the ear unprotected or to treat it in any way until I have inspected it in a week or ten days.

I feel certain that if more attention were given to the milder degrees of deafness and tinnitus which follow the milder forms of coryza, etc., one would avoid that troublesome form of deafness in later life—namely, the chronic catarrhal deafness, with its attendant intractable deafness and tinnitus.

Dr. Rodger advocates for the relief of a tubal mucopurulent discharge through an anterior perforation lavage of the Eustachian tube through a Eustachian catheter. The same treatment, of course, would apply to a tubal discharge after a radical mastoid operation. Success frequently follows this method of lavage, but it is at times somewhat irksome to the patient, and often the tube can be cleansed in the opposite direction—namely, by filling the external canal or radical mastoid cavity with the desired solution, allowing the patient to lie down with the affected ear uppermost, and, while in this position, to repeatedly perform "negative Valsalva" (that is, swallowing with the lips closed and nostrils occluded). Negative pressure is thus produced in the middle ear, and as the air is sucked out of the tube siphonage of the fluid takes place from the middle ear via the Eustachian tube into the nasopharynx.—I am, etc.,

Manchester, Sept. 26th.

Evipan on a Full Stomach

SIR,—I was interested in the article on evipan anaesthesia in ophthalmic surgery by Mr. T. K. Lyle and Dr. F. G. Fenton in your issue for September 29 (p. 589). It appears to me, however, that their views on loaded stomachs require modification. They state that "evipan may be given without danger with a partially full stomach." Again, in reporting a case: "Inhalation anaesthesia would have been impossible owing to the fact that the patient had recently had a meal."

In the considerable literature which has now accumulated relating to evipan deaths there are fatalities which have undoubtedly been caused by syncope from an over loaded stomach. One author (E. A. Voss, *Deut. med. Woch.*, 1933, No. 25) specifically calls attention to this danger. On general principles there seems to be no reason why a full stomach should be less dangerous with sodium evipan than with any other type of general anaesthesia.—I am, etc.,

London, N.W.S. Sept. 28th.

C. LANGTON HEWER.

Preliminary Ligation in Toxic Goitre

SIR,—Although in favour of preliminary ligation of toxic goitre are such authorities as Sir Thomas Dunhill Professor Wilkie, Mr. Geoffrey Keynes, etc., I should like to outline briefly my opinion on the subject. I agree entirely with Mr. Philpotts (September 22nd, p. 569) that the preliminary ligation should never be practised in cases of toxic goitre. I think that such an operation as trivial as it may seem, is only leading to trouble, or at least worthless.

In the last few years in the surgical clinic of Professor Lobenhoffer—one of the recognized German authorities on goitre—about eighty to a hundred operations on goitres, most of them toxic, have been performed every year, and in no case has the preliminary ligation of the arteries been practised. The mortality due to the operative shock was less than half per cent. The only two fatal cases I witnessed in this clinic were one in which a preliminary ligation was tried, and the other in which only one lobe of the gland was removed. As Mr. Howe points out, for the good success of the operation it is imperative to remove at least three-quarters of the gland. Even the very toxic patients support the operation very well. The operative shock is always less when large portions of the lobes of the thyroid gland are removed than in cases in which only one lobe is resected, and I therefore believe that an operation in two stages is also unnecessary. I think that neither the preliminary ligation nor the resection of one lobe of the gland will reduce to any large extent the amount of active gland, and for this reason the intervention for toxic goitre should be in one stage, and the removed tissue, as said before, should be over three-quarters of the gland.

The preliminary use of iodine is extremely useful for the success of the operation, and gives excellent results when administered for a sufficient period of time. Regarding the other point—that preliminary ligation should be practised as a test for the susceptibility of the patient to surgical trauma—it is impossible to judge the degree of susceptibility through this operation. In many patients the post-operative shock is greater when this small operation is performed than in the ordinary partial thyroidectomy. On the other hand, I believe that the psychological effect produced on the patient by trying to obtain his permission for the operation is not different whether he is asked to agree to a preliminary ligation of the arteries or to a proper operation on the thyroid. In conclusion, basing myself on my own experience on toxic

goitres, which extends over 150 cases with no mortality. I should like to state that I have always been able to obtain the patient's consent, the operation being performed under local anaesthesia, and I have always practised the operation in one stage by partial removal of a little more than three-quarters of the gland, although among the patients there have been cases of a very high degree of thyrotoxicosis, advanced age, or very low general condition.—I am, etc.,

Manchester, Sept. 24th.

G. BANKOFF.

The Swab in Diphtheria Diagnosis

SIR,—I hesitate to prolong the already lengthy correspondence on this subject, but I think it would be a pity if the net result of it were to shatter the general practitioner's confidence in yet another accepted clinical procedure.

No one knows better than the general practitioner that scientific tests are rarely a substitute for clinical observation, and that a negative swab does not preclude the disease when clinical signs are suspicious. On the other hand, a positive report always means that the patient is a potential danger either to himself or to others, or to both. Practising in a district where diphtheria has been almost endemic for several years, I have found the swab of very great assistance in the diagnosis of doubtful cases and in the detection of carriers.

In my experience of "sore throats" in relation to diphtheria there are three classes of cases to be considered: (1) those in which the diagnosis of diphtheria is certain, or almost so; (2) those in which no question of diphtheria arises; and (3) those in which doubt exists.

1. These cases are immediately given an injection of antitoxin—8,000 to 20,000 units, according to the severity and duration of the infection—and a swab is taken and examined for organisms of diphtheria and Vincent's angina (the other condition most likely to cause confusion).

2. These cases are treated on the appropriate lines. It is impracticable in a busy practice (and I think unnecessary) to swab all cases of sore throat—which may be anything from mildly injected fauces to an acute streptococcal pharyngitis or a recurring quinsy. If, however, diphtheria is prevalent locally, or the relatives express any uneasiness, a swab is taken, but no specific treatment is given pending a report.

3. Each of these cases must be judged on its own merits. The public health arrangements in this district are so good that I can almost always obtain the result of a direct smear examination within three hours, and a cultural report within twenty-four, and often less. Where the probability is not very great I wait for the direct smear report: if negative, it may be permissible to wait for the cultural report; but most of these cases receive antitoxin before the final report is received.

In all cases when diphtheria has been diagnosed and confirmed I immediately swab all the other members of the household, children and adults, and inject 2,000 units of antitoxin intramuscularly. Since adopting this procedure I have not had one single second case occurring in the same household. It seems likely that, even if a person is actually incubating the disease, an injection at this period may completely abort the attack. Moreover, if two swabs at intervals of two days are negative, and the person has had antitoxin injected, he may be safely released from quarantine.

It seems scarcely fair to attribute the high mortality from diphtheria to the dilatoriness of the general practitioner. Other more important causes are the delay of the relatives in summoning their doctor, and the initial virulence of the infecting strain of the Klebs-Loeffler bacillus. The remedy lies, first, in the education of the public to get immediate advice on every sore throat, and secondly, the provision by all local authorities of

facilities for the rapid examination of swabs and the free and ample supply of antitoxin to practitioners for prophylaxis and treatment. If the public fails to learn the children will have to be immunized. If the practitioners fail to utilize the facilities provided for them then the "area specialists" will come. But they will not only give advice on diagnosis; they will make the diagnosis and administer the treatment, and another useful sphere of activity will be denied to succeeding generations of general practitioners.—I am, etc.,

Liverpool, Sept. 22nd. A. G. C. FFOLLIOTT, M.B., B.Ch.

Haemorrhage from Peritonsillar Abscess

SIR,—Knowledge of anatomy may be obtained first hand, by dissection; second hand, from anatomical textbooks; or third hand, from other books containing abstracts or extracts from anatomical works. Mr. T. G. Wilson makes use of the last method, and then allows himself to be led astray by an obvious misprint. Reference elsewhere, or even to neighbouring passages in the book he quotes (Irwin Moore: *The Tonsils and Adenoids and their Diseases*), would show that the descending palatine artery should have been described as a branch not of the internal carotid, but of the internal maxillary artery, and therefore from the external carotid artery. His argument for ligation of the internal carotid artery therefore fails.—I am, etc.,

Canterbury, Sept. 29th.

THOMAS A. CLARKE.

SIR,—Mr. T. G. Wilson goes one better than Dr. Watson, in that he refers to one book for a reference to another book; his faith unshaken by the omission of either to mention a vessel which he finds among the various tissues brought away by the guillotine. (See the article on "The Post-operative Complications and Results of Tonsil and Adenoid Operations in Children" by Miss Elizabeth Nesbitt in your issue of September 15th.) But I am pleased to see that he confirms the existence of a vein where the Holmesian reasoning has already suggested it. If this vein exists, then to explain the persistent bleeding which is the subject of this argument it is only necessary to suppose that it behaves as veins notoriously often do. The alternative is to produce an artery where none can be shown by dissection, and then get it to behave as no artery can be made to do experimentally.

Personally, I have never seen arterial spurting in the tonsillar fossa anywhere except from the facial branch, but I have only too often had obviously venous bleeding shown to me as arterial because of pulsations in its flow transmitted from the great vessels close below it. However, if there is in Dublin a preparation showing the textbook blood supply of the tonsil I am very willing to go across to see it; I am quite unable to find one in this country.—I am, etc.,

London, W.1, Oct. 1st.

DENIS BROWNE.

Injuries of the Knee-joint

SIR,—I confess to have only a limited knowledge of the surgery of the knee-joint, but I flatter myself I have just sufficient to understand when one writes sense or otherwise. It was not I who wrote "locking in extension, etc.": the phrase is Mr. Stewart Woodman's, and as it is contradictory in terms it is consequently meaningless. He is confusing method with the result, means with the end. What I did suggest was that the history gave me a right to claim that the cartilage could be torn in full extension, the locking resulting afterwards.

Since my communication of May 5th my notice has been drawn to a paper by Mr. C. H. Fagge. Mr. Stewart Woodman will there find that Mr. Martin's advocacy of 1911 has not settled this question finally, as this paper was written in July, 1927, and is to be seen in the *British Journal of Surgery*, vol. xv. He may be astonished to find that there are well-known London surgeons who question Mr. Martin's theory. If he has not already seen this paper I recommend it to him, as he will find a well-sustained argument, and a reasonable hypothesis as to how the cartilage is torn. Whether one agrees or not it compels one's respect, whereas a bald statement such as "rupture takes place *always* in flexion" leaves one cold. Mr. Stewart Woodman wishes me to explain the mechanism of rupture. I should like him to essay the task. If he will do that, and lay his assertiveness aside, he will earn our thanks and command our regards. —I am, etc.,

Leeds, Sept. 30th.

J. STEWART.

The Medical Profession in Hungary

SIR,—I have just returned from the Annual Conference of the Association Professionnelle Internationale des Médecins at Paris, and I wish to bring to the notice of our Association some facts about the situation in Hungary which should cause grave concern to every organized medical body.

The representative of Hungary gave us a detailed history of what has been happening to the profession there in the last few years. Briefly, for some years the country has been suffering from the effects of the financial crisis to an extent which we can hardly conceive. Wages and salaries have been cut all round on several occasions, and the medical profession has suffered with the rest of the population. The reduction in the remuneration of insurance doctors amounts to something between 40 and 50 per cent. The last cut was made when the Government made drastic economies in order to save the health insurance system from bankruptcy. The doctors naturally expected that as the balance sheet of the "caisses" began to improve, so would the position of the medical profession. But they were cruelly deceived. Though the financial position of the "caisses" is now sensibly improved, the Government has peremptorily refused to consider the position of the doctors. But that is not all. The Government now intends to destroy the system of "free choice," which the profession thought it had, after a long struggle, established, and the emphatic protests of the Hungarian Medical Association have just been met by a decree ordering all doctors who derive any kind of remuneration from the State to leave the association. This involves nearly every doctor in the country—all insurance doctors, hospital doctors, university professors and teachers, and, of course, all military and Civil Service doctors.

The A.P.I.M. received this news with consternation. We were amazed that at this time of day the Government of any civilized country should deny to professional men the right of combination which is commonly accorded to workers of every kind. Doubtless the International Labour Office of the League of Nations, with which Hungary is connected, will have something to say about this extraordinary action.

Our Hungarian colleagues, crushed by real poverty but still resolute to preserve their civic rights, deserve, and will, I am sure, receive, the sympathy of every British doctor, as they did that of the representatives of fourteen national medical organizations present in Paris. —I am, etc.,

London, W., Oct. 2nd.

ALFRED COX.

Death and the Survival of Rights of Action

SIR,—I am glad to see your leading article on the above subject (September 29th, p. 600), and I quite agree with the writer's statement that "this change in the law is fraught with grave consequences to the medical profession." Why then did the medical profession take no steps to prevent it? Before the change was made I called the attention of the London and Counties Medical Protection Society to the matter, but nothing was done. Did the British Medical Association do anything?

I may be wrong, but I think the recent change in the law makes the widow, or other representatives, of a deceased doctor liable for alleged negligence of the doctor during his life. If this is so the consequences are more than grave. In a large proportion of cases there will be no evidence (in his absence) on the doctor's behalf, and the opportunity for blackmailing will be simply appalling. Already, as some of the judges seem fortunately to recognize, the expert blackmailer quite realizes that the law affords an efficient and safe engine for his purposes. —I am, etc.,

Lingfield, Surrey, Sept. 29th.

HUGH WOODS, M.D.

"Port Sanitation and Common Sense"

SIR,—In your issue of August 25th a ship surgeon airs his "grouses" against the port sanitary authorities. Though my experience as port medical officer was a temporary one of only some months' duration I feel qualified to question the justice of some of his views.

Ship surgeons, I imagine, are no different from the rest of the profession, and they comprise men good, bad, and indifferent; men with much experience and with little. Can the port authorities be certain that the ship surgeon (not to speak of the skipper of a ship carrying no doctor) can be relied on *in every case* to differentiate between (1) mild cholera and acute food poisoning, (2) an ordinary femoral adenitis and plague with a septic wound of the leg as a coincidence just to put one off, (3) severe chicken-pox and mild small-pox modified by vaccination? Port authorities have more experience of these "snags" than the average individual ship surgeon, of whom how many have had much experience of plague and cholera? I have omitted the possibility that several deaths from "pneumonia" on board may have been due to *B. pestis* and not to the pneumococcus. Hence the question, "Have you had any cases of illness aboard infectious or not?" If circumstances seem suspicious the authorities can pursue the matter.

"Ship Surgeon" complains of having to fill up a form at both ends of Suez Canal. Assuming the last part of call to have been Aden, surely infectious disease may break out aboard between Suez and Port Said. I see no reason for this complaint. As to the question whether the ship has picked up anybody or anything during the voyage—the ship might have picked up the crew (with their belongings) of an Arab dhow drifting unmanageable in the Red Sea, the crew being stricken with cholera acquired from the pilgrimage. In this case surely the ship could give the approximate position. The authorities are not dealing only with the surgeons of crack British liners. Certainly the surgeons of some foreign ships cannot be relied upon too far, and most ships carry no doctor. There cannot be a multitude of forms—for example, (1) for ships not carrying doctors, (2) for foreign ships carrying a doctor, (3) for British ships carrying a doctor who is (a) good, (b) bad, (c) indifferent.

I once boarded a ship belonging to a famous British line carrying a British doctor who assured me that he had no illness on board. He was not a good liar, and his assurance

was too emphatic. A tour of the ship disclosed several cases of severe small-pox, which were being deliberately concealed from me. Naturally I visited the ship with the utmost rigour of my powers, which were considerable, and reported the facts to the Board of Trade. I fancy it cost the company some thousands of pounds and the doctor his job. A week or two later I boarded a foreign liner. The doctor informed me that he had two cases of small-pox which had been isolated to the best of his ability, and that every soul aboard had been vaccinated. Naturally I did my best for this ship, allowing the discharge of cargo and of passengers on condition that they gave the address of their destination and reported daily to the health authorities during the incubation period. The surgeon of another British liner informed me that he had lost a passenger from retention of urine. Inquiries revealed the fact that before sailing the surgeon had pawned the ship's case of catheters.

In conclusion, I may add that I have been hauled out of the Orient Express at Brigue and subjected to medical inspection merely because my passport showed that I had recently been in Egypt, where some cases of plague had occurred.—I am, etc.,

Alexandria, Sept. 2nd.

"M.D."

Obituary

BARRY KEYTE TENISON COLLINS

M.A., M.D.Cantab., F.R.C.S.Ed., F.C.O.G.

Obstetrician and Gynaecologist, Cardiff Royal Infirmary; Lecturer in Obstetrics and Gynaecology, Welsh National School of Medicine

The death of Dr. Barry Tenison Collins, which occurred on September 24th from cerebral haemorrhage at the early age of 47, removes a prominent figure from the medical life of Cardiff and from his specialty. His father, the late Mr. Edward Tenison Collins, was one of the first to specialize in gynaecology in South Wales: he died only eight years ago.

After a distinguished war service in Gallipoli, Egypt, and East Africa as a captain in the R.A.M.C.(T.), Barry Collins returned to Cardiff and devoted himself entirely to the study and practice of his twin specialty. He was soon appointed to the junior honorary obstetrical and gynaecological staff of Cardiff Royal Infirmary, and in 1931 he was promoted to the senior staff when Sir Ewen Maclean resigned. He was also lecturer in the subject in the Welsh National School of Medicine, and with these appointments his reputation and his practice grew rapidly, so that he came to occupy a leading position in South Wales. He was a sound clinician, an experienced operator, and a clear and concise teacher; while as a colleague his cheerful, breezy presence was always welcome in any professional gathering.

His outside interests were many, and chief among them was his love of sailing: every spare moment was spent in his motor boat in the Bristol Channel. He was also a keen gardener, with quite a specialized knowledge of roses. His mechanical knowledge and ability was most marked, and he was always happy when dealing with some such problem in professional or domestic life. That a life of such varied interests should be cut off so tragically and at so early an age appears indeed hard. He leaves a widow and a daughter, to whom has gone out much deep and sincere sympathy from a very wide circle of personal and professional friends. The memorial service, in the chapel of Cardiff Royal Infirmary on September 27th, was attended by a large gathering, which included practically the entire medical and nursing staff of the Infirmary.

THE LATE PROFESSOR J. A. MILROY

Professor E. B. C. MAYRS writes from Belfast:

Professor J. A. Milroy inspired to an unusual degree the affection and esteem of all who knew him. Kindly and unassuming, his profound knowledge of biochemistry was always at the service of his colleagues, and their problems often made considerable demands on his time. Those who sought his advice were impressed by his familiarity with complex reactions, and with the less known literature of his subject. But his knowledge of science and philosophy extended far beyond the limits of biochemistry. He was a very careful worker; his name is a guarantee of accuracy in his published work. It is hard to believe that his place can ever be filled. We have lost a good friend, and his modesty and charm will live in our memory.

Dr. THOMPSON CAMPBELL died on September 22nd in Leeds, after a short illness, at the age of 62. Born in Glasgow, he was educated at Hutchinson's Grammar School and Glasgow University, where he took honours in many of his classes, among them the Sir William Gairdner prize in clinical medicine. He graduated M.D., with distinction, in 1900, and subsequently held the appointments of house-physician and house-surgeon at the Western Infirmary, Glasgow. He made a voyage to India, and afterwards settled down to his life's work. He was superintendent at Quarriers' Homes, Bridge of Weir, where he did excellent work in organizing and introducing new methods in the treatment of tuberculous patients, and was afterwards appointed superintendent at Ochil Hills Sanatorium, Kinross. This was a new institution, built and equipped with all modern appliances. In 1912 he entered the service of the West Riding of Yorkshire as chief tuberculosis officer, and worked for seven years organizing dispensaries for the examination of tuberculous patients. In 1919 he was appointed medical superintendent at Middleton Sanatorium, Ilkley, Yorkshire. In 1931 he became one of the consultant tuberculosis officers for the West Riding. He travelled extensively in Switzerland, Germany, and America, studying all methods in the treatment of tuberculosis in the various sanatoria. A former colleague writes: Middleton-in-Wharfedale Sanatorium is one of the largest institutions of its kind in the country, having 300 beds for the treatment of male patients, and it was here that Campbell found scope for his energy, enthusiasm, and skill in his life's work. A man of unbounded energy, he could not bear fools gladly, and had no compromise with error or slackness in work. He did not spare himself. He knew every patient in his sanatorium, could tell you off-hand his name, condition of his chest, including x-ray examination, and whether his sputum was positive or negative. Campbell himself knew too well what it meant to have tuberculosis, and the more ill a patient was it only drew forth the best he could give. He was essentially a man who was never weary in well-doing. He cared little for the things of pleasure, and money he spent freely in helping and relieving patients whom he knew to be in distress. Now that he is gone he will be greatly missed by many throughout the West Riding of Yorkshire, where he was held in great respect and affection.

Dr. HENRY WILLIAM BEEDHAM, who died on July 31st at the age of 66, had been a member of the British Medical Association for exactly forty years. He studied medicine at Cambridge and the London Hospital, and graduated M.A., M.B., and B.Ch. in 1895, having taken the L.S.A. in 1893. He was engaged in general practice for some years, first at Norwich, then at West Hampstead and in Cricklewood. In 1914 he took up ophthalmic work only, and held appointments as clinical assistant at Moorfields, the Royal Eye Hospital, Southwark, and at King's College Hospital, Denmark Hill. He took the diploma D.O.M.S. soon after its institution. At the commencement of the Great War Dr. Beedham was the

first man in West Hampstead to enrol as a special constable. He went to France in 1915 under the Red Cross Society, and in 1916 became a temporary lieutenant in the R.A.M.C.; he was promoted captain, and in 1917 was invalided home. Dr. Beedham was a man greatly beloved by all who had the privilege of working with him. For fifteen years he was vicar's warden at Emmanuel Church, West Hampstead, and for six years had been chairman of the Medical Board of the Church Missionary Society. He will be much missed by a large circle of friends.

We regret to announce the death, on September 26th, of Dr. JOHN WILLIAM ENSOR. Dr. Ensor was educated at Epsom College and Guy's, and qualified in 1899. Soon afterwards he started practice in Birmingham. Ensor moved to the new district of Golder's Green in 1911, and saw Hendon develop from a rural village to a borough of over 100,000 inhabitants. In practice he was extremely successful, and on his retirement in March of this year, owing to ill-health, he received a remarkable demonstration of affection from his patients, who presented him with an illuminated address and a motor car to mark their appreciation of his services. After twenty-two years' membership of the British Medical Association he was made chairman of the Hendon Division in 1931. For many years he served on the medical staff of the King Edward Memorial Hospital, Hendon. His colleagues have a very deep and real sense of sorrow at his loss. He is survived by his wife and two children.

Universities and Colleges

UNIVERSITY OF LONDON

Lectures

A course of three lectures, entitled "Forty Years of Gynaecological Endocrinology," will be given by Professor Ludwig Fraenkel, late director of the Women's Clinic in the University of Breslau, at University College Hospital Medical School, on October 31st and November 2nd and 5th, at 5.30 p.m.

The Heath Clark Lectures, on "Malaria in Europe," will be given by Dr. L. W. Hackett, assistant director of the International Health Division of the Rockefeller Foundation, at the London School of Hygiene and Tropical Medicine, on December 3rd, 4th, 5th, 6th, and 7th, at 5 p.m.

A course of three lectures, on "Newer Aspects of Gastritis and its Consequences," will be given by Professor Knud Faber of the University of Copenhagen, at Guy's Hospital Medical School, on November 6th, 8th, and 9th, at 5 p.m. At the first lecture the chair will be taken by Dr. Arthur F. Hurst.

A course of three lectures, on "Some Chemical Problems related to Pharmacology," will be given by Professor G. Barger, D.Sc., F.R.S., of the University of Edinburgh, at the London (Royal Free Hospital) School of Medicine for Women, on November 1st, 2nd, and 9th, at 5.30 p.m.

A course of three lectures, on "Physiological Equilibrium," will be given by Professor L. J. Henderson of the Fatigue Laboratory, Harvard University, at University College, on October 16th, 17th, and 18th, at 5 p.m.

A lecture on "Inflammation of the Maxillary Antrum and other Accessory Sinuses (Some Clinical Manifestations of its Pathology)" will be given by Mr. Herbert Tilley, at the Royal Society of Medicine, on Thursday, November 1st, at 5 p.m.

A public lecture on "Hippocrates and the Hippocratic Tradition in Modern Medicine," by Dr. A. P. Cavadias, will be given at King's College, Strand, W.C., on Friday, October 19th, at 5.30 p.m.

UNIVERSITY OF LEEDS

The following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B. (Part I). T. K. Cooke, F. A. Crossill, M. A. Kader, C. V. Light, O. Scarborough, F. A. Shackleton, Helene E. Sykes, J. D. F. Thornton, H. L. L. Wilson (Part II). F. B. Coates, G. M. Davies, R. S. Illingworth, B. Jackson, K. I. Johnstone, G. J. Kearney, E. Lodge, L. Rabinovitch, J. T. Rhodes, H. R. Rollin, L. A. Westwood (Part III): K. I. Johnstone (second-class honours), F. B. Coates, G. M. Davies, R. S. Illingworth, B. Jackson, G. J. Kearney, E. Lodge, J. T. Rhodes, L. A. Westwood, W. Zemsky.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—A. J. Bain, H. Burt, J. M. Frew.

D.P.H.—J. Fielding, G. P. Holderness, J. Q. Mountain.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

VARIATION OF THE PARTNERSHIP AGREEMENT

The Partnership Act, 1890 (Section 19), lays down that the mutual rights and duties of partners, whether they are set out in an agreement or left to be defined by the Act, may be varied by the consent of all the partners.

This consent need not be given expressly, but may be inferred from a course of dealing. The partners may, in fact, be quite unaware that they have consented to a variation, but if they have behaved as though they had consented, then the variation is binding on them. The court inquires in each case what the actual *de facto* rights and duties were, not how they appeared on paper.

The most usual form of variation to come before the courts is a failure to take the accounts at the intervals specified in the articles. The written agreement often lays down that the accounts shall be taken and signed yearly or half-yearly, and that if a partner dies a final account shall be taken as at the date of his death. When the accounts have not been taken as they should have been the court tries to do justice to the representatives of the deceased.

For instance, in *Simmons v. Leonard* (1844) the articles provided that an account should be taken every year. A partner died, and in the dissolution proceedings it appeared that the partners had never settled an account at all. The court ordered a general account to be taken down to the death of the deceased partner.

In *Pettyt v. Janeson* (1819) the accounts were to be taken every Lady Day. For the first few years they were so taken, but the settlements became irregular, and when a partner died in February, 1813, the last account was found to have been settled on November 5th, 1811. The court held that, as both parties had considered this a binding settlement, the next one ought to have been taken on November 5th, 1812, and awarded the deceased partner's estate a share of the profits up to that date.

Articles sometimes also provide for a periodical valuation, and disputes have arisen because the partners have not exactly carried out the provisions of the clause which governs it.

In *Coventry v. Barclay* (1863) an annual account and valuation had to be "made and fully finished" between the partners, and was binding on them when it was finished and signed by all. A partner died two months after the valuation had been taken; he had not been present, nor had he signed or expressly approved it, but it had been taken in the usual way, and there was nothing to show that he would probably not have accepted it. His executors claimed that it was an arbitrary valuation and he had not accepted it; they asked for a new valuation. Lord Westbury, Lord Chancellor, said that whether the method of taking the valuation agreed with the articles or not, yet, as it had always been followed without deviation or objection, it was valid and binding on the partners. If it was not the method prescribed in the articles, then it was evidence of a new agreement between the partners. The deceased partner had accepted and agreed to this valuation; it had been fully finished and settled between the partners, and if the deceased had not signed it he should have done so. As equity assumes that a thing is done when it ought to have been done, the deceased had, for the purposes of equity, signed the valuation, and it was as binding on him and his representatives as if he had.

It is not necessary for the partners to persist for a long time in a course of conduct inconsistent with the articles; it is only necessary that they shall all have clearly intended to supersede them. The court will not, however, assume that the articles have been varied merely because a provision has been waived once or for a short time only. Sometimes the partners seem to have observed a set of conditions not laid down in the articles but stricter than the existing provisions—such as taking a daily account in the management of the Covent Garden Opera House.

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), the second on June 23rd (p. 1145), the third on July 7th (p. 42), the fourth on July 21st (p. 141), and the fifth on September 22nd (p. 574).

(*Const v. Harris*, 1824). In this event one partner cannot claim as a right that this variation should be continued; the decision is one for the whole firm. Needless to say, many disputes would be avoided if all partners (1) kept in mind the main provisions of their articles, and (2) regularized every variation by putting it in writing and signing it, or, better still, by getting their solicitor to draft an appropriate amendment to the articles.

RELATIONS OF PARTNERS TO OUTSIDE PERSONS

For the purpose of the business of the partnership every partner is an agent of the firm. Anything he does in the ordinary course of the firm's business binds the firm and the other partners. If, for instance, he orders a supply of drugs or medical appliances in the name of the firm, the firm must pay for them. The only exception is a double one: when he has in fact no authority to act for the firm in the particular matter in hand, and the person with whom he is dealing either knows that he has no authority or does not know or believe him to be a partner. Both conditions must be fulfilled. Whether he has authority or not, he still binds the firm if the person with whom he is dealing thinks he has. If he has no authority, or has acted outside the scope of his authority, the firm can, of course, claim compensation from him for the expense to which he has put them. The firm is not bound if he pledges its credit without authority for a purpose apparently not connected with its ordinary course of business—for example, if he placed in its name a large order for wine for the third party is supposed to assume that he has no authority to do so. The principle is that the firm is not bound if the third party knows or has reason to know that the partner has no authority. If, for instance, the partners have agreed that one of them shall pledge the firm's credit only under certain conditions, a person who has notice of this agreement cannot claim against the firm if he gives credit in violation of those conditions.

Every partner is liable, jointly with the other partners, for all debts and obligations which the firm incurs while he is a partner. In Scotland the law is stricter, for each partner is severally liable—that is to say, he is responsible for the whole of the debts of the partnership and not only for his own share. After his death his estate is severally liable in England as well as in Scotland; in England his own creditors have priority over partnership creditors, but in Scotland the partnership debts and his separate debts rank together.

FIRM'S LIABILITY FOR NEGLIGENCE OF PARTNER

In a medical partnership a partner does not often have occasion to pledge the credit of the firm, and its work is so definitely limited to professional services that the question of whether a partner is acting in the course of its business or not hardly ever arises. A fact which concerns medical partners far more closely is that the whole firm and every member severally is liable for any damage caused by the wrongful act or omission of any partner acting in the ordinary course of its business, or with its authority. A patient dissatisfied by the treatment of one partner can sue the whole firm, and if he succeeds each and every partner is liable for the damages and costs, and the property of any one can be taken in execution of the judgement. The partner against whom the negligence is proved must indemnify the firm, but he may not be in a position to do so. Moreover, even if the patient loses his case he may have no money to pay the firm's costs, which will then fall on all the partners, because the partner whose conduct is complained of has done no wrong and therefore cannot be called on to indemnify the firm. Even if the patient does pay the costs, he does not reimburse the firm for the whole expense it has suffered, for a litigant, successful as well as unsuccessful, usually has to pay his own solicitor's costs.

Hence the vital necessity for every member of a medical partnership—even more vital, if possible, than for a solitary practitioner—to belong to a defence society. If an action is brought against a partnership for the alleged negligence or misconduct of a partner who is not a member of a defence society, the societies to which the other

partners belong would in all probability refuse to assist them. It is not necessary that all the partners should belong to the same society, for the two largest bodies have a reciprocal arrangement under which they act as one, but membership of the same society by all the partners has many obvious advantages and offers a ready means of settling any dispute between the partners without expense to them.

In the same way, any admission or representation made by any partner concerning the partnership affairs, and in the ordinary course of its business, is evidence against the firm. For this reason, if the conduct of any partner is being called in question by someone outside the partnership, the other partners should exercise the strictest discretion in speaking of the matter. A chance word spoken by any of them, even to a person who is not apparently interested, may have the most awkward consequences for them all.

Innocent partners cannot be fined or imprisoned for the criminal conduct of one of their number, but if some person is injured by that conduct, and it is in the ordinary course of their business, he can bring a civil action against any or all of them.

The Services

COMMISSIONS IN THE R.A.M.C.

The War Office announces that applications are invited* from medical men for appointment to commissions in the Royal Army Medical Corps.

Candidates will be selected for commissions without competitive examination, and will be required to present themselves in London for interview and physical examination on or about October 25th, 1934. They must be registered under the Medical Acts, and normally must not be over the age of 28 years.

Successful candidates will in the first instance be given short service commissions for five years, at the end of which period they may either retire with a gratuity of £1,000 or apply for a permanent commission. Permanent commissions will be given to officers selected from among those who wish to make the Army their permanent career.

Full particulars of the conditions of service and emoluments, also forms of application, may be obtained on application, either by letter or in person, to the Assistant Director-General, Army Medical Services, the War Office, London, S.W.1.

DEATHS IN THE SERVICES

Major-General Percy Carr-White, C.B.E., Madras Medical Service (ret.), died at Sedghill, Wilts, on August 6th, aged 69. He was born on June 20th, 1865, the son of William Alfred White, Esq., merchant, of Sydenham, and was educated at St. Thomas's and at Edinburgh, where he graduated M.B., C.M. in 1889, subsequently taking the F.R.C.S.Ed. in 1903 and the D.T.M. at Liverpool in 1909. Entering the I.M.S. as surgeon on March 31st, 1890, he became colonel on June 7th, 1916, and major-general on December 8th, 1919, retiring on October 18th, 1921. He served in the third Burmese War in 1891-2, with the Irrawaddy column (medal with clasp); on the North-West Frontier of India, in the Tachi campaign of 1897-8 (medal with clasp); and again on the North-West Frontier and in Afghanistan in 1919, when he was mentioned in dispatches in the *London Gazette* of August 3rd, 1920, and received the C.B.E. He was appointed honorary physician to the King on October 31st, 1918.

Colonel Alan Edmondson Tate, C.S.I., C.M.G., late R.A.M.C., died at Bexhill on September 3rd, aged 75. He was born at Ripley, Surrey, on July 5th, 1859, the son of the Rev. C. R. Tate, rector of Trent, Dorset, was educated at Merchant Taylors', at Bishop's Stortford School, and at the Middlesex Hospital, and took the M.R.C.S., and L.S.A. in 1882. Entering the Army as surgeon on August 4th, 1883, he reached the rank of colonel on December 31st, 1912, and retired on December 26th, 1917. He served in the Burma War in 1886-9 (frontier medal with two clasps); in the Chital campaign of 1895, with the relief force (medal with clasp); and in the South African War in 1899-1901, when he took part in operations in the Transvaal, the Orange Free

State, and Cape Colony, including the relief of Kimberley, the actions of Paardeberg, Poplar Grove, Karee Siding, Zand River, Johannesburg, Pretoria, Diamond Hill, Wittebergen, and Colesberg, receiving the Queen's medal with six clasps. In the war of 1914-18 he served as an A.D.M.S., was mentioned in dispatches in the *London Gazette* of October 19th, 1916, and received the C.M.G. in 1916 and the C.S.I. on September 9th, 1919. He was staff surgeon to Lord Kitchener, Commander-in-Chief in India, in 1903-7, and honorary surgeon to the Viceroy in 1912-17. In 1889 he married Zaidee, daughter of Frank White, Esq. She survives him, with one son, Lieut. Commander H. R. Tate, R.N., and one daughter, Mrs. Charles Jennings of Avisford, Arundel.

Lieut.-Colonel James Farquharson MacLaren, Bengal Medical Service (ret.), died suddenly at Allahabad on August 5th, aged 79. He was born on October 22nd, 1854, the son of the late Dr. MacLaren of Blairgowrie, and was educated at Edinburgh, where he graduated M.B., C.M. in 1877. Entering the I.M.S. as surgeon on April 2nd, 1881, he became lieutenant-colonel after twenty years' service, and retired on June 24th, 1911. He served in the Sudan campaign of 1885, in the Red Sea column, was present at the actions of Hashin and Tamai, and received the Egyptian medal, with a clasp, and the Khedive's bronze star. The rest of his service was spent in civil employ in the North-West, now the United Provinces, where he was for many years civil surgeon of Allahabad. After his retirement he remained there as surgeon to an Indian rajah. Some years ago he acquired the estate of Dalnabreck, Kirkmichael, Blairgowrie.

Lieut.-Colonel Winthrop Benjamin Browning, C.I.E., Madras Medical Service (ret.), died at Exmouth on September 15th, aged 79. He was born on July 6th, 1855, the son of the late Benjamin Winthrop Browning of Baggotstown, County Limerick, was educated at the City of Dublin Hospital, and took the L.R.C.S.I. and L.R.C.P. in 1879. Entering the I.M.S. on March 31st, 1880, he became lieutenant-colonel after twenty years' service, and retired on May 17th, 1910. After a couple of years' military duty the rest of his service was spent in civil employ in the Madras Presidency, almost entirely in the Madras General Hospital and Medical College. There he held the posts successively of professor of medical jurisprudence, assistant physician, second surgeon, and finally first surgeon and professor of surgery, and latterly also principal of Madras Medical College. He served as surgeon to three Governors of Madras in succession—Lord Wenlock, Sir Arthur Lawley, and Lord Amphil. He received the C.I.E. on December 31st, 1898. After retirement he settled at Fermoy, County Cork. In 1887 he married Annie Georgina, daughter of Colonel Kenlis-Fergus Stevenson, and had three sons.

Lieut.-Colonel Samuel Esmond Prall, Bombay Medical Service (ret.), died at Hythe on September 15th, aged 72. He was born on April 19th, 1862, the son of Dr. Samuel Prall of West Malling, was educated at Guy's Hospital, and took the M.R.C.S. in 1885, the L.R.C.P.Lond. in 1886, and the M.B., with honours, and the B.S.Lond. in 1887. Entering the I.M.S. as surgeon on September 29th, 1888, he became lieutenant-colonel after twenty years' service, and retired on March 26th, 1921. He served in the war of 1914-18, and was mentioned in dispatches in the *London Gazette* of March 7th, 1918.

Lieut.-Colonel Evelyn Charles Hepper, Indian Medical Service (ret.), died at Beaumont, Guernsey, on September 16th, aged 57. He was born on December 10th, 1876, was educated at Bart's, and took the M.R.C.S., L.R.C.P.Lond. in 1900. Entering the I.M.S. as lieutenant on June 27th, 1901, he became lieutenant-colonel on December 27th, 1920, and retired on September 1st, 1931. He served in the Zaka Khel campaign on the North-West Frontier of India in 1908, receiving the frontier medal with a clasp. In 1913 he got civil employ in the United Provinces, but in the following year was recalled to military duty to serve in the war of 1914-18. After the war he rejoined the United Provinces, and served there until his retirement.

Dr. Arthur Batoum Zorab, late I.M.S., died at Southampton on September 1st, aged 54. He was born on April 18th, 1880, the son of the late Lieut.-Colonel J. M. Zorab, I.M.S., was educated at Guy's, and took the M.B., B.S.Lond. and the M.R.C.S., L.R.C.P.Lond. in 1906. After serving as chief clinical assistant in the ophthalmic department at Guy's, he entered the I.M.S. as lieutenant on July 27th, 1907, but resigned two years later, on September 26th, 1909, and settled at Southampton, where he practised as an ophthalmic surgeon. He was honorary surgeon to the Free Eye Hospital, Southampton, and honorary ophthalmic surgeon to the Royal Hants County Hospital at Winchester.

Medical News

Four lectures on the rheumatic diseases will be delivered by Dr. J. Alison Glover at Gresham College, Basinghall Street, E.C., on October 9th, 10th, 11th, and 12th at 6 p.m. Admission free.

Dame Janet Campbell has been invited by the Canadian Council on Child and Family Welfare, with the approval of the Dominion Government, to visit Canada during October and November in the interest of maternity and child welfare, and she sails for Quebec to-day, Saturday, October 6th.

A meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine will be held on Tuesday, October 9th, at 5 p.m., when Professor J. H. Burn will deliver his presidential address on "The Control of the Blood Pressure." On October 12th, at 8.30 p.m., Mr. Ransom Pickard will give his presidential address before the Section of Ophthalmology, on "The Causation of Herpes Ophthalmicus."

A meeting of the Paddington Medical Society will be held at the Great Western Royal Hotel, Paddington, W., on Tuesday, October 9th, at 9 p.m., when Professor F. Langmead will deliver an address on "The Significance of High Blood Pressure."

The Harben Lectures will be delivered in the Lecture Hall of the Royal Institute of Public Health, 23, Queen Square, W.C., at 4 p.m. on October 8th, 9th, and 10th by Dr. W. J. Tulloch, professor of bacteriology, University of St. Andrews, on "The Diagnosis of Small-pox and the Investigation of Vaccinia by Laboratory Methods." No tickets of admission are required.

The opening meeting of the Illuminating Engineering Society will be held at the Lighting Service Bureau, 2, Savoy Hill, Strand, W.C., at 6 p.m. on Tuesday, October 9th. After the presidential address by Mr. H. Hepworth Thompson, a report on progress in illuminating engineering, prepared by the Technical Committee, will be presented, and various exhibits shown.

Two special lectures on "The Operative Treatment of Facial Palsy" (illustrated by cinema films) will be delivered at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Wednesday and Thursday, October 10th and 11th, at 5 p.m., by Dr. Arthur Baldwin Duel, F.A.C.S., senior surgeon-director of the Manhattan Eye, Ear, and Throat Hospital, New York.

The fifth winter post-graduate session at the Hampstead General and North-West London Hospital, Haverstock Hill, N.W.3, will open on Wednesday, October 17th, at 3 p.m., with an address by Sir Henry Brackenbury on "Patient and Doctor." Lectures will be given on Wednesday from October 24th to December 12th, at 4 p.m.

The annual meeting of the Société Française d'Orthopédie will be held at the Paris Faculty of Medicine on October 12th, when the following questions will be discussed: the funnel-shaped thorax, introduced by Dr. Garnier of Paris, and treatment of spastic paralysis, introduced by Drs. Roudel of Marseilles and Delchet of Brussels.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that lecture-demonstrations will be given at 11, Chandos Street, W., at 2.30 p.m. on October 9th and 16th. Courses of instruction include a week-end course on diseases of the heart and lungs at the Royal Chest Hospital, occupying the whole of October 13th and 14th; medicine and surgery, at the Metropolitan General Hospital, from October 8th to 20th, 10.30 a.m. to 6.30 p.m.; cardiology at the National Hospital for Diseases of the Heart, October 8th to 20th, occupying the whole of each day; ophthalmology at the Royal Westminster Ophthalmic Hospital, October 15th to November 3rd, every afternoon; gynaecology at the Chelsea Hospital for Women, October 22nd to November 3rd; neurology at the West End Hospital for Nervous Diseases, October 29th to November 3rd; and two week-end courses, one on clinical surgery at the Royal Albert Dock Hospital, October 20th and 21st, and the second on chest diseases

at the Hospital for Consumption, Brompton, October 27th and 28th. These courses are open only to members and associates of the Fellowship.

The People's League of Health has arranged the following lectures in connexion with the Borough of South-west's health week: October 8th, "The Laws of Health," Dr. Leslie J. Harris; October 9th, "Eyes," Mr. A. F. MacCallan; October 10th, "Does it matter what we Eat?" Professor V. H. Mottram; October 11th, "Teeth—How They Come and Why They Go," Mr. Francis V. Macquire; October 12th, "Preventable Disease in the Home," Sir Bruce Bruce-Porter; October 13th, "Every Man His Own Doctor," Dr. Harry Campbell. The meetings will be held at the lecture hall, Manor Place Baths, S.E.17, at 8 p.m.

University College Hospital Medical School has arranged a programme of post-graduate demonstrations for the benefit of old students on Thursday and Friday, October 11th and 12th, from 10 a.m. to 4 p.m. At 4.15 p.m. on October 12th the annual general meeting of the Old Students' Club will be held in the Medical School, under the chairmanship of the president, Surgeon Vice-Admiral Sir Arthur Gaskell. At 7.30 p.m. the same day the annual dinner (12s. 6d. exclusive of wines) will be held in the library of the Medical School. The annual dinner of the University College Hospital Medical Women's Association will be held at the Piccadilly Hotel on Friday, October 12th, at 7.45 p.m., preceded by the annual general meeting at 7.15.

The National Hospital, Queen Square, W.C., has arranged a post-graduate course from Monday, October 8th, to Friday, December 7th. The course will include out-patient clinics each week-day, except Saturday, at 2 p.m., lectures and clinical demonstrations each week-day, except Saturday, at 3.30 p.m.; demonstrations on the pathology of the nervous system, on Wednesdays and Thursdays at 12 noon, on the anatomy of the nervous system, on Mondays at 12 noon, and on methods of clinical examination, on Thursdays at 5 p.m. The fee for the course is £10 10s.; for those who hold perpetual tickets, and for clinical clerks, £8 8s.

At a sessional meeting of the Royal Sanitary Institute at Sunderland on Friday, October 12th, a discussion on "Vermin and Slum Clearance" will be opened by Dr. A. S. Hebblethwaite, medical officer of health for Sunderland; and a discussion on "Anaemias and Preventive Medicine" will be introduced by Dr. H. A. Cookson. Mr. W. T. Creswell, K.C., will preside over the meeting, which begins at 5 p.m., in the Town Hall.

The third congress of the Latin Medical Press will be held in Paris under the presidency of Professor G. Etienne of Nancy, from October 17th to the 21st, when the following papers, among others, will be read by French, Belgian, Spanish, Portuguese, and Rumanian representatives: the relations of the medical press with pharmaceutical advertisements; the scientific and moral responsibility of the Latin medical press; and the technique and presentation of a medical journal. Further information can be had from the general secretary, Dr. L. M. Pierra, L'Hérmitage, Luxeuil, Haute Saône, France.

The fortieth Italian Congress of Internal Medicine will be held at Rome under the presidency of Professor Cesare Frugoni from October 17th to 20th, when the following papers will be read: "Meteorism," by Professors N. Pende and M. Bufano; "Vaccine and Non-specific Treatment of Infectious Diseases," by Professors A. Ferrata and G. Boeri; "Bronchiectasis" (in conjunction with the Italian Society of Surgery), by Professors A. Omodei Zorini, R. Alessandri, F. Lassagna, and A. Vallebona; and "Pleurisy in the Army," by Major R. D'Alessandro. Further information can be obtained from the general secretary, Professor Arnaldo Pozzi, R. Clinica Medica, Rome.

A committee consisting of ophthalmologists and otolaryngologists has been formed at Marseilles to commemorate the first operation performed under local cocaine anaesthesia in October, 1884. The ceremony will take place on October 27th. Further information can be obtained from Dr. Roche, Marseilles.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The Address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Catarrhal Jaundice following T.A.B. Inoculation

Dr. ARTHUR D. SPENCE (London, E.C.1) writes: It would be interesting to know whether others have had the experience described below. I have given many hundreds of anti-typhoid inoculations, but have not had catarrhal jaundice occur before, though in the course of typhoid fever in the East we sometimes saw varying degrees of jaundice. A young assistant in a merchant firm in Bangkok had the usual 0.5 c.cm. first T.A.B. inoculation preparatory to his return to the East, on Thursday, August 9th. On Saturday night he had a severe rigor and vomiting, and later a temperature of 102° F. Next day he developed a typical catarrhal jaundice, with occasional vomiting. He later became deeply jaundiced and the itching of the skin was very marked. The jaundice ran a usual course, but I did not care to give him his second dose, and he left for the East on August 23rd. The vaccine was prepared at the Lister Institute of Preventive Medicine.

Treatment of Disseminated Sclerosis

"M.D., D.P.H." writes from Essex: Campolon has, I understand, been used with some success in subacute degeneration of the cord in cases of pernicious anaemia. I should be pleased to hear if any of your readers has tried this preparation in disseminated sclerosis and with what result. If success can be attained in the former case, why not in the latter?

Nail-biting

"M. P." writes from Cornwall: A man who was a persistent nail-biter in his boyhood and for long spells in later years found the habit impossible to control had gall-stones removed when over 50 and now for ten years has had no tendency whatever to resume the practice. I suggest that in many if not in all cases there is a centre of irritation which should be sought and treated. As the gall-bladder would appear to be the likeliest site for the irritation it may one day be accepted that nail-biting is a symptom of gall-stones!

Income Tax

Purchase of Additional Practice

"G.P." purchased the goodwill of a practice from "X," a retiring practitioner, the consideration being the payment to "X" of half the fees received from his patients for the following two years. The inspector of taxes insists on treating "G.P." as having commenced a new practice as from the date of the amalgamation. Is this legally correct?

Yes. The practice must be regarded as a new one, and "G.P." is assessable on his (presumably) increased profits as from the date of amalgamation of the practices. He cannot exclude the cash received and handed on to "X" because that represents the capital amount he is

paying for the additional connexion. The hardship so far as "G.P." is concerned is that he is in effect forced into the position of having to pay tax on income (that is, the fees due for work done after the amalgamation) before it is received, or if received, has partially been expended in capital payment.

Tax on Interest Paid

"J. C. C." is liable for payment to an insurance company of interest as follows: gross amount, £32, less-income tax, £8—net amount payable, £24. He asks why he should pay income tax every year, since the loan was received once only.

* The payment of tax by "J. C. C." has nothing to do with the receipt of the loan, which was a "capital" transaction, but is merely the way in which the tax due from the company on the £32 reaches the Revenue. If there were no tax "J. C. C." would pay the company £32; as it is, he pays the company £24 and the Revenue £8—that is, £32 in all. In other words, he does not ultimately bear the £8 tax; he is merely the channel by which it reaches the proper quarter.

LETTERS, NOTES, ETC.

Diagnosis of Endocrine Dysfunction

"A. G." (Bathford) writes: I venture to suggest that an observation in connexion with abnormal functioning of the endocrine glands may be of more extended interest than has perhaps been realized. The following passage occurs in *The Tides of Life* (R. G. Hoskins): "There is some evidence that the pancreas of the developing foetus may in a measure function in the latter part of pregnancy to correct the insulin deficiency in the diabetic mother. In experimental animals suffering from pancreatic deficiency events may progress fairly satisfactorily until the birth of the offspring, after which death of the mother from acute insulin deficiency may promptly take place (Carlson). In conformity with the foregoing, Mazer and Goldstein have recently noted indisputable evidence of over-production of insulin in an infant of a diabetic mother for several days after its birth." (Italics mine.) The phenomenon of amelioration of symptoms during pregnancy is not confined to diabetes alone, and this suggestion that a normal foetus may be supplying a glandular deficiency in the mother seems an interesting explanation of what may be occurring in all these cases. If this were so, and since the infant shows signs of over-activity of the crucial gland for a few days after birth, the question arises whether, by observing the newborn infants of mothers suffering from various complaints, it might not be possible to ascertain which gland in the mother is lacking in efficiency. The disease in which such an observation would perhaps be of the greatest interest is the primary form of rheumatoid arthritis. Of this complaint Dr. W. S. C. Copeman writes: "Symptoms will often clear up during a pregnancy which occurs in the course of the disease, but return in most cases with redoubled vigour after parturition." (*The Treatment of Rheumatism in General Practice*). If the offspring of such mothers were found to show signs of some glandular over-activity, that might prove quite a useful pointer in the study of the arthritis enigma. In other conditions also, such as epilepsy and allergy, where remission of symptoms occurs during pregnancy, it might be possible by the above means to learn something either of the aetiology of the disease or of the constitutional weakness of the particular patient.

Graham Lusk

The name of Graham Lusk is familiar to our readers through his book *Elements of the Science of Nutrition*. Those desiring to learn something of his career and personality may be recommended to turn to a comprehensive article by Amos E. Light in the *Yale Journal of Biology and Medicine* May, 1934, vi, 487, which is illustrated by a striking photograph and contains a full bibliography. The son of a distinguished obstetrician, Lusk was born in Bridgeport, Connecticut, in 1866. Deafness led him to take up chemistry rather than medicine as a career, and he began by studying chemical engineering at Columbia School of Mines. At Munich he had the good fortune to work under Carl von Voit, whom he never failed to visit when subsequently travelling in Europe. In 1895 he became professor of physiology at Yale, where his department consisted of one room only, which he cleaned himself. He later occupied the chairs of physiology at Bellevue Hospital Medical

College and at Cornell University, and in 1912 became director of the Russell-Sage Institute of Pathology at New York. He retired just before his death, which occurred on July 18th, 1932, at the age of 66. His more important contributions to physiology include his researches on clinical calorimetry, specific dynamic action of proteins, phlorhizin glycosuria, and diabetes mellitus. He was the founder and first president of the Harvey Society. Throughout his career he advocated the migration of directors and instructors from one school to another to lower the possibility of either becoming too self-centred.

Blood Pressure Risks

"L.R.C.P." writes from Co. Durham: With reference to the correspondence in the *Journal* of September 15th, under the headings "Is High Blood Pressure a Risk?" and "Is the Taking of Blood Pressure a Risk?" the answer is, in my experience, "Yes" to the first query, and "No" to the second. I have very little doubt that the fatalities mentioned by Dr. Hunter are coincidences such as have occurred during serum administration. I have taken several thousand blood pressure readings, including two hundred of a patient who died from angina pectoris. I took readings from the same patient during two attacks. He died a few hours later in another attack. There were no ill effects from my observations extending over a period of twenty years. In the second tragic occurrence the blood pressure reading was 140/120, too low a systolic pressure for a patient with such a high diastolic reading, and in my opinion means a weakened or degenerated myocardium. Confirmation may be obtained from the character of the breathing and the rhythm of the pulse. If the breathing is audible with or without separation of the lips and teeth and the lower intercostal spaces are indrawn, coupled with a poor exercise tolerance, and if on auscultating over the cardiac area for at least two minutes a silence is detected during a complete cardiac cycle, or an alteration in the rhythm, where two normal beats are followed rapidly by five or six small beats—then I believe the myocardium to be extensively degenerated, and sudden death may follow.

Substitute for Oiled Silk

Dr. W. WASHBOURN, C.B.E. (Blackfriars, Gloucester), writes: A patient has recently called my attention to the virtues of a substance named "gelaphane," as a substitute for oiled silk for fomentations, etc. I have given it a good trial and find it more efficient, and far cheaper, costing about 1s. 8d. a square yard, as against 3s. for oiled silk.

* We have made inquiries, and learn that the substance Dr. Washbourn mentions is manufactured by Gelaphane, Ltd., Severn Road, Gloucester.

Playfair's Probe as Pipe-cleaner

Dr. DOUGLAS SEATON (Leeds) writes: I should like to congratulate Dr. D. V. Latham (September 29th, p. 618) on his ingenuity in using pipe-cleaners in place of a Playfair's probe. I have not had any occasion to use this instrument for its original purpose for some years, but have found it a very efficient pipe-cleaner.

Disclaimer

Dr. A. M. VALERIE BONHOTE (Tadworth) writes: I am not in any way responsible for the publication, in lay newspapers, of an extract from my letter which was published in the *British Medical Journal* of last week on page 618.

* We sympathize with Dr. Bonhote: but she is not the first (and will not, we fear, be the last) to suffer from unsought publicity of this kind.

Corrigendum

Our attention has been drawn to a mistake in the article "Numbers of the Medical Profession," published on September 1st (p. 389). In the sentence beginning "According to statistics published last year by the International Labour Office the country with the most medical practitioners is England, with 1 doctor to every 822 inhabitants" the figure should have been 1,490. The reference is the *Quarterly Bulletin of the Health Organization of the League of Nations*, vol. ii, No. 4, December, 1933.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals will be found at pages 51, 52, 53, 56, and 57 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 54 and 55. A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 192.

THE CLINICAL IMPORTANCE OF ACHLORHYDRIA*

BY

ARTHUR F. HURST, M.A., M.D. OXON., F.R.C.P.

SENIOR PHYSICIAN TO GUY'S HOSPITAL

So much has been written on achlorhydia during the last twelve years that it might be thought that very little more could be said about it. But I think there is still room to discuss it from a somewhat wider point of view than has been possible until recently, by considering how it arises and how it comes to be associated with such a remarkable variety of diseases, and, most important of all, how the latter can be prevented by preventing the development of achlorhydia, or, when this fails, by curing the underlying condition instead of merely treating it symptomatically by the substitution of artificial for natural gastric juice. In order to do this I shall have to begin by referring to some fundamental physiological facts concerning the functions of gastric juice.

Functions of the Gastric Juice

1. *Peptic Digestion.*—The glands of the body of the stomach contain two kinds of cells: chief cells, which secrete pepsin, and parietal or oxyntic cells, which secrete hydrochloric acid. The most obvious function of the hydrochloric acid is to activate the pepsin so that it can digest proteins. This is, however, not an essential function, as tryptic activity in the small intestines is so efficient that digestion of meat is unimpaired in complete achlorhydia and after gastrectomy.

2. *Antiseptic Action.*—The antiseptic action of the acid is more important. It destroys streptococci and other organisms which are swallowed with saliva from the mouth and with mucus from the nose and pharynx. It also helps to protect against infection with bacteria present in food and drink. There is a good deal of evidence to show that bacillary and amoebic dysentery occur much more commonly in people with achlorhydia or hypochlorhydia than in those with a normal secretion of acid (Camps, 1933), and the same probably holds good for typhoid and other enteric infections and for cholera. I am confident that the Services would save a great deal of invaliding if they took the precaution of giving test-meals to all men before sending them to the Tropics in order to eliminate those with achlorhydia.

Knott (1927) has shown that the increased alkalinity of the contents of the small intestine which results from achlorhydia favours its invasion with *B. coli* from the colon; this organism is consequently found in large numbers in the duodenum, which is normally quite sterile. The spread of *B. coli* occurs with extraordinary rapidity. The stomach and duodenum are infected within a few hours of the perforation of a gastric or duodenal ulcer and the consequent inhibition of the secretion and movements of the stomach (Löhr, 1924). This explains why the peritoneum is sterile if an operation is performed within six hours of perforation but after that becomes progressively more heavily infected.

Infection of the small intestine with streptococci from above and with *B. coli* from below, combined with the mechanical irritation of the mucous membrane by food which is insufficiently softened and broken up owing to the deficient quantity

and solvent activity of the gastric juice, is very apt to lead to chronic enteritis. Moreover, when the gastritis which caused the achlorhydia is a result of the action of some swallowed irritant, the small intestine is liable to be damaged at the same time as the stomach. The functions of the small intestine are difficult to investigate and consequently very little is known about their derangements, but we are gradually accumulating evidence that many symptoms ascribed to the stomach and colon are really due to disorders of the small intestine. Thus chronic diarrhoea is frequently associated with achlorhydia; though these cases, which are sometimes wrongly diagnosed as colitis, are now generally regarded as gastrogenous in origin because of the rapid disappearance of the diarrhoea with acid, true enteritis is often present as well.

Cholecystitis is frequently associated with achlorhydia, and is, I believe, generally due to an ascending *B. coli* infection from the duodenum (Hurst, 1932). Even when free acid is present in the stomach the symptoms often date from an attack of acute gastritis, in which achlorhydia may occur temporarily, as Beaumont (1833) demonstrated in his observations on the effect of a drinking bout on Alexis St. Martin, or from pregnancy, which is also often associated with temporary achlorhydia. On restoration of normal gastric secretion the infection dies out from the duodenum, leaving, however, the seeds for the development of inflammation and stone formation in the gall-bladder. The nausea which is sometimes associated with achlorhydia is probably often due to the accompanying cholecystitis.

3. *Haemopoiesis.* (a) *Absorption of Iron.*—The diet taken by most people contains amply sufficient iron to maintain the normal percentage of haemoglobin in the blood. When, however, the diet is deficient or excessive quantities of blood are lost in menstruation or from other sources, a microcytic anaemia results if an insufficient proportion of the iron in the food is absorbed. This may occur in achlorhydia, but it is uncertain whether it is due to there being no hydrochloric acid to convert the organic iron in the food to a form suitable for absorption, or to a failure of absorption by the small intestine, which is so frequently in an unhealthy condition when achlorhydia is present. The latter is probably the true cause, as the simple administration of hydrochloric acid has no effect on the anaemia in such cases, though when large doses of inorganic iron are given the intestines are still capable of absorbing a sufficient proportion for rapid recovery to take place. (b) *Production of Haemopoietin.*—Castle has proved that the gastric juice contains a substance, the "intrinsic factor," which acts on something present in protein food, the "extrinsic factor," to produce the normal stimulant for the formation of red corpuscles by the bone marrow, its absence leading to Addisonian (pernicious) anaemia. Wilkinson's (1933) investigations indicate that the intrinsic factor, which he calls "haemopoietin," is an enzyme. According to Meulengracht (1934) it is produced by the glands in the pyloric end of the stomach and probably the fundus, which contain none of the chief and parietal cells of the glands of the body of the stomach, which secrete respectively pepsin and hydrochloric acid.

4. *Production of Neuropoietin.*—The gastric juice contains an enzyme which is produced by the same glands and acts

* Read in opening a discussion in the Section of Medicine at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

in the same way as haemopoietin to form a substance which is essential for the normal nutrition of the central nervous system. This enzyme, which may be called "neuropoietin," is not identical with haemopoietin, as either may be absent from the gastric juice whilst the other is present. Its absence leads to degeneration of the posterior and lateral columns of the spinal cord. Though the resulting disease is generally associated sooner or later with Addison's anaemia, this is not invariably the case, and degeneration of the cord was found in only 85 per cent. of fatal cases of Addison's anaemia in the days before the introduction of treatment by liver. Salus and Reimann found haemopoietin in the gastric juice of five patients with subacute combined degeneration of the cord and achlorhydria whose blood picture was normal, though it was absent in seven other patients who had Addison's anaemia in addition to the spinal degeneration.

Pathogenesis of Achlorhydria

Out of every hundred normal people about ten secrete more and ten secrete less hydrochloric acid than the remaining eighty (Bennett and Ryle, 1920). The hyperchlorhydria and hypochlorhydria are expressions of what I have called respectively the hypersthenic and hyposthenic gastric constitutions, and both are often familial. They are compatible with perfect general health and good digestion, but whereas the 80 per cent. of people with the average type of stomach are likely to pass through life without developing any serious gastric disorder, most of those with hyperchlorhydria suffer sooner or later from gastric or duodenal ulcer, and most of those with hypochlorhydria develop achlorhydria with its many associated troubles. In both cases this is generally the result of the chronic gastritis which follows prolonged mechanical or chemical irritation of the gastric mucous membrane. Mechanical irritation may be caused by insufficient mastication when food is bolted or dentures are deficient, and by the consumption of excess of coarse vegetable material, including the roughage which is so widely and unwisely recommended for constipation.

The chief chemical irritants are alcohol, especially when taken undiluted on an empty stomach or mixed with other irritants in the form of cocktails; strong tea and coffee; excess of curry, pickles, pepper, and mustard; drugs such as bromide, iodide, mercury, digitalis, quinine, and salicylates, which are taken continuously for long periods; and the poisons which are swallowed when too many cigarettes are smoked. Chronic gastritis is also a common sequel of the acute gastritis caused by food poisoning and by the excretion of toxins by the gastric mucous membrane in acute infections such as gastric influenza, scarlet fever, and septicaemia. These exciting causes are so universal that very few of those predisposed by the hypersthenic or hyposthenic gastric constitution escape. Consequently 10 per cent. of people dying after the age of 40 are found to have an active gastric or duodenal ulcer or the scar of a healed ulcer (Stewart, 1929), and at least 10 per cent. of people over 40 have achlorhydria (Hartfall, 1932).

It is still uncertain whether achlorhydria is ever congenital and due to an inborn error of secretion. In their investigations on a hundred healthy students Bennett and Ryle found that four of the ten with deficient gastric secretion had complete achlorhydria. Combining their statistics with those of Baird, Campbell, and Hern (1924), Wright (1924), and Apperly and Semmins (1928), it is found that 3.4 per cent. of 497 healthy students and children had achlorhydria. But the achlorhydria may have been acquired as a result of acute gastro-enteritis or some general infection in infancy or early childhood. Achlorhydria is often familial; the associated abnormality of the gastric mucous membrane rather than any constitutional weakness of the bone marrow or spinal cord is the

cause of the frequent occurrence of Addison's anaemia and subacute combined degeneration of the spinal cord in more than one member of a family. Records have been published of about 140 families in which two or more members in one to four generations were affected with Addison's anaemia with or without subacute combined degeneration of the cord, and fifty-nine families in which one of these diseases occurred in one or more members of a family and achlorhydria in others, some of whom were young children (Hurst, 1927, Conner, 1930, Wilkinson and Brockbank, 1931). Ellis and Frank have both observed twins suffering from Addison's anaemia. All these facts point strongly to the achylia being constitutional. It is possible, however, that the constitutional condition was an extreme degree of hypochlorhydria, which would be likely to result in achlorhydria at an early age and in Addison's anaemia or combined degeneration of the cord in later life in several members of a family. That achlorhydria may be a sequel of familial hypochlorhydria was shown by two sisters under my care with achlorhydria; treatment of the gastritis led to restoration of the secretion of acid in one but not in the other. Moreover, Wilkinson and others have found that hypochlorhydria as well as achlorhydria is frequently present in other members of the family of patients with Addison's anaemia.

The strongest evidence in favour of the existence of a true constitutional achylia is the occasional discovery of normal, or almost normal, gastric mucous membrane in patients with Addison's anaemia. Passey (1922) found normal oxyntic cells and no evidence of inflammation in a fragment of gastric mucous membrane removed during an operation for appendicitis in a patient of mine with Addison's anaemia and achlorhydria.

Effect of Gastritis on the Gastric Juice

The gastric mucous membrane attempts to protect itself against mechanical and chemical irritants by the secretion of mucus. This mucus is probably produced by the tall columnar cells which line the whole surface of the stomach; it is independent of the dissolved mucus which is always present in normal gastric juice and is presumably secreted by some of the cells of the gastric glands. It is such a weak alkali that its buffer action is hardly appreciable, but it contains sufficient sodium bicarbonate to neutralize some of the acid of the gastric juice (Bonis, 1930). At the same time some of the tenacious mucus adheres to the surface of the mucous membrane and blocks the mouths of the secreting tubules, thus reducing the quantity of gastric juice which can gain access to the lumen of the stomach. The inflammation of the gastric mucous membrane depresses the functional activity of its glands. The oxyntic cells are the most delicate, so that the hydrochloric acid is the first constituent to be seriously affected. If the healthy stomach produced a gastric juice of average or more than average acidity, the reduction of acidity brought about in these three ways is of no importance. If, however, the healthy stomach secretes a gastric juice of less than average acidity, as occurs in individuals with the hyposthenic gastric constitution, achlorhydria results.

In about 60 per cent. of cases the excess of mucus is sufficient by itself to account for the achlorhydria, as on giving a second test-meal after washing the stomach with plain water so as to dislodge the mucus, free acid is found in some of the fractions. In an additional 20 per cent. of cases removal of the exciting causes of the gastritis and treatment of the inflamed mucous membrane by lavage are followed by restoration of normal secretory activity of the stomach.

In rare cases the initial inflammation is so intense that some or all of the oxyntic cells are at once destroyed.

In severe chronic gastritis with achlorhydria the mucous membrane is invaded by streptococci swallowed from the mouth, and progressive atrophy of the glands takes place. Restoration of secretion is then impossible, and the injection of histamine produces no response, even if all active inflammation is overcome by treatment, the condition being, in fact, a true achylia gastrica and not merely achlorhydria. In true achylia most of the cells secreting pepsin are also destroyed.

The production of haemopoietin and neuropoietin by the mucous membrane of the pyloric end and fundus of the stomach is very rarely diminished sufficiently to give rise to Addison's anaemia and subacute combined degeneration of the spinal cord, except in the severe cases of gastritis in which true achylia occurs. In exceptional cases of Addison's anaemia the damage to the mucous membrane is not irreparable. I have had three cases in which the secretion of hydrochloric acid returned as a result of treatment of the gastritis; in one of these, recorded by Shaw in 1926, the patient is still after eleven years completely well with normal gastric juice and normal blood, though he has never taken stomach extract or liver. In the other two cases the restoration of gastric acidity was not accompanied by any return of haemopoietin production, and the patients still require liver. Similar cases of restoration of acidity have since been recorded by McPeak and Neighbors, Wilkinson, Heeres, Seyderhelm and Opitz, and Davidson. In Davidson's case haemopoietin is now also secreted, so his patient can be classed with my first case as an example of complete recovery. In those cases in which the secretion of hydrochloric acid, but not of haemopoietin, returns, the glands in the pyloric end and fundus of the stomach, but not those of the body, are presumably degenerated, just as they must be in the 1 per cent. of patients with Addison's anaemia in whom free acid is present throughout. Hydrochloric acid continues to be secreted in subacute combined degeneration of the cord, though no neuropoietin is produced, in about the same proportion of cases.

Post-Operative Achlorhydria

1. *Gastro-jejunostomy*.—Partial neutralization by the alkaline duodenal secretions which enter the stomach through the stoma after gastro-jejunostomy, together with the increased rapidity of evacuating, reduces the quantity of free acid present. As, however, the operation is generally performed for duodenal ulcer, in which hyperchlorhydria is almost always present, it is rare for the fall to be sufficient to lead to achlorhydria. When achlorhydria is present after gastro-jejunostomy, the operation has generally been needlessly performed on a patient who already had achlorhydria, or on one with a chronic gastric ulcer in whom the original hyperchlorhydria had been replaced by hypochlorhydria as a result of chronic gastritis. In rare instances, however, the hyperchlorhydria of a duodenal ulcer may be followed by achlorhydria after gastro-jejunostomy. This appears to be due to exceptional severity of the chronic gastritis which always occurs when excess of bile enters the stomach, but which fortunately does not often give rise to symptoms.

Though the achlorhydria makes it impossible for an anastomotic ulcer to develop, it is not an unmixed blessing. Chronic enteritis with diarrhoea and chronic cholecystitis are occasional sequels. Simple achlorhydric anaemia may develop under the same conditions as those which lead to its occurrence in ordinary achlorhydria. I have seen one case of the kind in a man (Cosin and Hurst, 1930) and one in a woman, and one male and fifteen female cases have been recorded by Witts, Davies, and Meulen-

gracht, the haemoglobin varying between 24 and 70 per cent. and the interval after the operation between four and twenty-five years.

The gastritis following the operation may be of such severity that the gastric juice is not merely neutralized, but is no longer secreted, and the achylia may then be associated with absence of haemopoietin or neuropoietin. I know of nine cases in which these diseases followed gastro-jejunostomy; in the majority nothing was known about the gastric acidity before the operation, but one patient of mine had a duodenal ulcer with hyperchlorhydria and developed achylia with Addison's anaemia and subacute combined degeneration of the cord eighteen months after gastro-jejunostomy (Glanvill and Hurst, 1930), and Salus (1932) has recorded two fatal cases of subacute combined degeneration of the cord without anaemia which appeared fifteen years after gastro-jejunostomy, test-meals having shown that free acid was present before but absent after the operations.

2. *Complete and Partial Gastrectomy*.—One would expect the complete achylia which follows removal of the entire stomach to be followed before long by Addison's anaemia and subacute combined degeneration of the cord, owing to the loss of the glands which produce haemopoietin and neuropoietin. This occurred in cases described by Dennig, Hochrein, Poole and Foster, Ungley, and possibly in a patient of Moynihan's. On the other hand, Mr. H. B. Butler of Guildford tells me that a patient on whom he performed complete gastrectomy in 1926 has shown no signs of anaemia or nervous disorder since, although he has had neither stomach extract nor liver, and Walters (1933) described a similar case two years after operation.

Partial gastrectomy is frequently followed by simple achlorhydric anaemia. As the fundus probably secretes haemopoietin and neuropoietin, Addison's anaemia and subacute combined degeneration of the cord develop only in the exceptional cases in which severe atrophic chronic gastritis involves the remaining portion of the stomach. In 1931 I collected five cases of this kind, and since then at least seven others have been recorded. We always give a test-meal after operations on the stomach. If achlorhydria is present there is less need for prolonged care in diet than if hyperchlorhydria persists, as an anastomotic ulcer cannot develop, but in such cases we advise the patients to take 30 grains of iron and ammonium citrate three times a day for one week in every four, and some form of liver at least once a week for the rest of their lives, as a safeguard against the development of simple and Addisonian anaemia.

Achlorhydria and Carcinoma of the Stomach

Achlorhydria is present in about 65 per cent. of patients with carcinoma of the stomach. It was formerly believed that the achlorhydria was a result of the carcinoma, but in my Schorstein Lecture of 1929 I brought forward evidence to show that the achlorhydria is really caused by chronic gastritis which is present before the growth develops, the growth being a result of malignant degeneration of the chronically inflamed mucous membrane. All the evidence I have been able to collect since then confirms this theory. I know of no case in which free acid was found when a growth was first recognized and disappeared at a later date. The hyperchlorhydria remained unaltered in three patients with chronic ulcers which subsequently underwent malignant degeneration. In another case of ulcer-cancer, in which operation was refused, the acidity actually rose whilst the carcinoma was growing, presumably owing to the favourable effect on the associated gastritis of the diet and lavage which

kept the patient comparatively free from pain. A similar rise was observed by Pollard and Bloomfield (1931) in two cases of carcinoma after an interval of four and six months respectively. On the other hand, I have had four patients in whom achlorhydria was known to be present before the carcinoma developed, and I have found records of at least nineteen similar cases.

As carcinoma follows chronic achlorhydric gastritis, which may also cause simple anaemia, Addison's anaemia, and subacute combined degeneration of the cord, it is natural that these conditions sometimes occur with or precede the development of a growth. Thus carcinoma of the stomach developed in a patient of mine who had recovered from severe simple achlorhydric anaemia as a result of treatment with iron. The occasional association of carcinoma of the stomach with Addison's anaemia and subacute combined degeneration of the cord has long been recognized; I have myself seen five such cases, and at least twenty-two others have been recorded (Wilkinson). Now that most patients with Addison's anaemia can be kept free from recurrence indefinitely with stomach extract or liver, an increasing number of them will develop carcinoma of the stomach if my theory is correct. I have seen two such cases, in one of which carcinoma developed nine years after the onset and four years after the symptomatic cure of Addison's anaemia as a result of treatment with liver (Plummer, 1931). Dyke and Harvey (1933) found that three out of fifty-two patients with Addison's anaemia under treatment died in a period of five years from carcinoma of the stomach, and from inquiries I have made among physicians who have had many cases of Addison's anaemia under their care I find that a good many cases of this kind have now been observed.

The association of cancer and Addison's anaemia with achlorhydria was strikingly demonstrated in the history of a family described by Borovanská-Felklová, in which a man died of carcinoma of the stomach, his eldest son had Addison's anaemia and subsequently developed carcinoma of the stomach, two other sons had Addison's anaemia, and the fourth had achlorhydria alone.

In almost every undoubted case of ulcer-cancer in which a test-meal has been given free acid was present in spite of the fact that the history was often very long, whereas when the evidence pointed against the growth being secondary to a simple ulcer, achlorhydria was generally present, even if the test-meal was given at a very early stage of the disease (Orator, 1925, Stewart, 1931). Free hydrochloric acid was found in all but one of eleven cases of carcinoma of the stomach with more than eighteen months' history, whereas seventeen out of nineteen with a history of less than six months had achlorhydria; these statistics of my own (1931) are confirmed by those of Pantan and Tidy (1910), Orator, and Stewart. The chance of long survival after a successful gastrectomy is greater in patients with achlorhydria than in those with free acid (Hartman, 1921), although the reverse would be the case if achlorhydria was the result of the presence of a growth in a stomach which had hitherto produced free acid.

Cramer (1934) has shown that the total incidence of cancer is the same in all nations, both sexes, and in all classes, although there are wide differences in the relative frequency in which different organs are involved. This indicates that a constitutional tendency for cancer to develop exists in a certain proportion of human beings, and that the organ involved must depend upon local conditions. I have long believed that cancer never develops in a healthy stomach. In about 25 per cent. of cases malignant degeneration occurs in a simple ulcer and in the remainder it occurs in chronically inflamed mucous membrane, the former being always associated with the presence of free hydrochloric acid and the

latter generally with achlorhydria, though the free acid and the achlorhydria have, *per se*, nothing to do with it. It is the association of the constitutional tendency to cancer with one form of the hypersthenic gastric constitution on the one hand and with the hyposthenic gastric constitution on the other which results in cancer of the stomach. At present we have no knowledge of how the cancer constitution can be controlled, but it should be possible to prevent the development of cancer of the stomach by preventing chronic gastric ulcer and chronic gastritis, or, when this fails, recognizing and overcoming them at as early a stage as possible. Prophylaxis consists in preventing the various exciting causes of ulcer and gastritis which have already been described, and which, trivial as they may appear to be, are none the less of supreme importance.

Treatment

Until recently it was assumed that the discovery of achlorhydria was an indication for treatment with hydrochloric acid. It is true that many of the associated symptoms can be overcome by this means, but the underlying gastritis remains unaltered and may become progressively worse. It may finally affect the production of haemopoietin and neuropoietin, and the chronically inflamed mucous membrane may undergo malignant degeneration. It is therefore clear that the gastritis itself should always be treated. This has resulted in the return of secretion of acid in no less than 82 per cent. of our patients (Hartfall, 1932), who thus have the advantage of secreting their own gastric juice instead of having to buy it from their chemist, and the treatment may also prevent the development of Addison's anaemia, subacute combined degeneration of the cord, and carcinoma of the stomach.

Pyorrhoea must be completely overcome by conservative measures when possible, but otherwise by extraction; infected tonsils must be enucleated, and sinus infection must receive appropriate treatment. It is a good plan to give the patient nothing but milk or milky feeds for the first few days of treatment. In the severe cases in which blood is present in some of the fractions of a test-meal, or, as occurs more frequently, occult blood is found only in the stools, the strict diet should be continued till the blood has disappeared. As a rule, two or three weeks suffice, but in exceptional cases of hypertrophic or polypoid gastritis, in which the danger of malignant degeneration is probably considerable, a longer period may be required. The patient is subsequently given an un-irritating diet for six months, or, if the achlorhydria persists, for the rest of his life. He should be teetotal at first and later should confine his drinks to lunch and dinner or immediately after. He should never indulge in spirits or cocktails on an empty stomach. Smoking should be prohibited during the period of strict treatment; after that it may be allowed in moderation, preferably after meals, and the swallowing of irritating juice should be prevented by the use of clean pipes and of cigarettes with a wool plug in the mouthpiece.

The stomach should be washed out every morning with dilute hydrogen peroxide (1 drachm to the pint) until the washings are clear. The treatment should be continued until no mucus is brought away. It is then given on alternate days, later twice a week, and finally once a week for two or three months. In severe haemorrhagic cases 1/2 to 1 part per thousand silver nitrate solution should be used instead of hydrogen peroxide in the early stages. When the washings no longer contain mucus a second test-meal must be given, as it is only necessary to prescribe hydrochloric acid for the 20 per cent. of patients in whom achlorhydria is found to be still present.

From 1 to 2 drachms of the dilute acid (*British Pharmacopoeia*) are given in 5 to 10 ounces of water, to which the juice and pulp of an orange have been added. As in these residual cases the secretion of pepsin is generally reduced, a saltspoonful should be added to the mixture. The first dose should be taken fasting before breakfast, when its antiseptic action is not impaired by partial neutralization with alkaline food. The second is given as a beverage with lunch, and the third with dinner. Patients rapidly get accustomed to it, and should rarely have any difficulty in taking it regularly for the rest of their lives.

Conclusion

Thirty years ago Professor Knud Faber of Copenhagen came to the conclusion that achlorhydria is always secondary to gastritis, and he has maintained it ever since. When shortly after the war I first became interested in the subject I was so impressed with the constitutional factor that I was inclined to doubt whether gastritis was of any importance at all. I now realize that gastritis and constitutional factors are of equal importance. Without gastritis there is no achlorhydria, but gastritis does not cause achlorhydria unless the patient is predisposed by having the hyposthenic gastric constitution. Gastritis in the presence of the hypersthenic gastric constitution may lead to duodenal ulcer and gastric ulcer, and a gastric ulcer may become malignant, but achlorhydria does not develop. It is the conjunction of the apparently trivial causes of gastritis with the hyposthenic gastric constitution which leads to achlorhydria, and the conjunction of these with the constitutional predisposition to cancer which leads to carcinoma of the stomach.

I expect that this is the last time there will be a discussion on achlorhydria, for the problem has shifted, and we must in future discuss gastritis, its causation, early diagnosis, treatment, and prophylaxis, just as we discuss nephritis rather than albuminuria. It is gastritis which causes achlorhydria, and gastritis, not achlorhydria, which causes Addison's anaemia and subacute combined degeneration of the cord and predisposes to carcinoma of the stomach. The prophylaxis of gastritis is the prophylaxis of these diseases. We may therefore look forward to the time when the prevention of gastritis, and, when prevention fails, its early recognition and adequate treatment, will lead to the disappearance of cancer of the stomach, which every day of the year claims over forty victims in Great Britain.

ACUTE AND CHRONIC SPRAINS*

BY

W. ROWLEY BRISTOW, F.R.C.S.
 ORTHOPAEDIC SURGEON, ST. THOMAS'S HOSPITAL

I think the Section is wise to have selected for discussion "Acute and Chronic Sprains," so common in occurrence, but so little discussed, that it is well for us to review our ideas and be sure that they are based on sound principles. These conditions and their treatment did not attract us in our student days; they were not big enough. Who ever heard of an out-patient dresser, or even a house-surgeon, who was really interested in a sprained ankle? And yet when the doctor starts in practice it is the minor injury, far more than major surgery, which forms the bulk of the surgical side of his practice. His reputation as a good doctor will be made not by his knowledge and management of cerebral tumours, but by his handling of the sprained wrist and the Colles fracture. I would focus your attention on what passes as minor surgery, and would remind you that it is only "minor" within the shelter of the hospital walls, and assumes very different proportions when we are faced with the same problem in after-life.

We will consider the acute sprain and its management, and then pass on to the consideration of those sprains which fail to clear up and become chronic. But, before entering into a discussion on the diagnosis and treatment, certain points in the anatomy and physiology of joints must be recalled in order to be sure that our treatment is based on a clear appreciation of the underlying principles.

Physiology of Joint Movements

The essential factor to recognize is the importance of the muscles. Many complex structures go to form a joint—bones, cartilage, ligaments, and so on—but for any real understanding of the pathology of joints the role of the muscles must be emphasized.

Muscle is the first line of defence of a joint against injury, and protects it all the time against the repeated though small injuries which are met with in everyday life. If a false step is taken in walking and the balance momentarily lost, it is muscle action which prevents a strain or sprain of the ankle- or knee-joint if we are to avoid injury. If the force is too great, or is applied for too long a time, the muscle gives way; it can no longer protect the joint, and the force then falls on the second line of defence—namely, the ligaments. Here once again consequences depend on the degree of force. If the latter is slight, the ligament may withstand strain, and no ill effect will follow. If it is moderate, some fibres of the ligament will tear, generally from one or other attachment, and a sprained joint results. If the force be severe, a ligament may tear in its entirety, perhaps taking with it a small flake of bone from the point of its insertion or tearing away from its periosteal attachment, and a sprained joint results. Finally, if the force be very severe or prolonged, first the muscle, then the ligament, and finally the bone itself yields, resulting in a fracture.

This conception must be remembered, and we must guard against thinking of a fracture as a broken bone, or of a sprain as a torn ligament; we must not forget the all-important fact that it is on muscle that the first strain falls. Indeed, the fracture is often the least important part of the injury—that is, when considered from the point of view of solution of continuity in the bone. For example, a sprained back with fracture of the transverse

* Read in opening a discussion in the Section of Orthopaedics at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

process of a vertebra is, academically speaking, a fracture, but it is the muscle injury, the tearing of muscle attachment, the haematoma, and the effect on soft parts which should take precedence in determining the appropriate treatment.

Partial rupture of a ligament, the tearing of a few fibres, is far more common than a complete rupture. The determination of the degree of injury is essential to a rational treatment of that injury. A complete tearing away of the attachment of the internal lateral ligament of the knee—in my experience a rare event—will necessitate at least prolonged fixation and protection, or even operative repair. The far more common tearing of a few fibres at the femoral attachment of this ligament is ill suited to such prolonged fixation, and recovers more quickly if appropriate means are taken to aid and encourage early functional use of the joint.

Diagnosis

The diagnosis of the acute sprain is self-evident, and in practice it is only necessary to exclude fracture. Careful case-taking or history is of importance, and the clinical examination must be thorough. The ultimate diagnosis of fracture will be decided by x-ray examination, but the clinician should be able to form a fair idea whether the sprain is uncomplicated or whether a fracture without displacement coexists. The site of maximum tenderness on pressure will generally give the clue. Tenderness over a ligamentous attachment is strong presumptive evidence of sprain; localized tenderness over the bone, at some other point, suggests fracture.

It cannot be emphasized too strongly or repeated too often that x-ray examination is an essential part of the clinical investigation of every patient in whom the symptoms complained of follow injury. Failure to observe this rule may lead the practitioner into all kinds of trouble. It will not help him to say that the fracture found at some later examination is trivial, and that its earlier discovery would not have altered his treatment. He must foresee in every injury the possibility of a medico-legal action, and he must safeguard himself as well as his patient. The case in which an injury to the back has resulted in a crush fracture of the spine is within the experience of most of us. How often does this injury pass unrecognized, with what disastrous results, and yet how simple is the x-ray diagnosis. The split fracture of the fibula without displacement and the fracture of the carpal scaphoid are common examples of bone injury frequently undiagnosed because of the failure to have an x-ray examination.

A further word of warning is needed. An x-ray plate in itself will not suffice. The x-ray examination must be thorough. The radiographs must be taken in two planes, or, if need be, stereoscopically. In certain situations a radiograph of the equivalent joint on the uninjured side should be taken for comparison; this is useful in young patients in whom the epiphyses are still unjoined—for example, the child's elbow. And the x-ray plates must be interpreted by someone accustomed and experienced in such interpretation. He may be a radiologist or a surgeon; he must know what he is looking for, so that he reads neither too little nor too much in the picture.

Treatment of Acute Sprains

The line of treatment on which most of us were brought up in our hospital days leaves much to be desired and is rightly criticized. Hot lead lotion, evaporating lotion, a bandage, and rest sufficed for the bulk of patients in our casualty departments, and formed the recognized treatment of the textbooks. If we excluded a fracture by x-ray examination, we were content to let these patients work out their own salvation on these or similar lines.

The more general introduction of massage and physical treatment in our hospitals improved matters, but unfortunately these departments do not seem to attract the average medical student, who may well pass through his whole career without any very clear idea of what they accomplish, because he does not take the trouble to attend. Those of us who are called upon to lecture or to demonstrate to post-graduates must be struck by the interest and the eagerness to learn the modern treatment of these simple injuries which is shown by the practising doctor.

Now what should be the treatment of an acute sprain? As an example, let us imagine an acute inversion sprain of the ankle seen an hour or two after the injury. The region of the ankle is swollen and painful, and there is tenderness on pressure in front and to the outer side of the joint. The anterior fasciculus of the external lateral ligament is partly torn from its attachment. The principles of treatment can be described under three headings: (1) pressure to limit the swelling; (2) protection to limit and prevent further damage; and (3) encouragement of function to promote recovery.

PRESSURE

Pressure can be applied by firm bandaging over layers of cotton-wool, and in the example chosen the bandage should include the heel. The more usually applied figure-of-eight bandage omitting the heel is insufficient and fails to give support just where it is most needed. This pressure bandage, if applied early, limits the amount of the swelling; if the ankle is already swollen, it is useful in getting rid of such swelling.

PROTECTION

The firm bandaging protects for the first thirty-six hours, and then, if necessary, this should be replaced by adhesive plaster strapping. The strapping starts above the ankle on the inner side, passes down under the heel, and up on the outer side. The foot is held slightly everted to take strain off the injured ligament while this support is being applied. Many layers, each superimposing the other by about one-third, are used. The strapping does not interfere with function, but protects the early stages of repair from undue strain and further damage and gives the patient a sense of comfort and security.

If the sprain be only slight strapping may be dispensed with, and the support of the compression bandage will in itself suffice. It is all a question of degree. While a very slight strain will not need protection because the muscle recovery is rapid, the moderate or severe one will recover more quickly with support; the latter does not hamper movement, which is physiological and to be encouraged. Further protection may be provided by what is called "wedging the heel" and floating it out. This is seldom needed unless the sprain is a frequently recurring one, such as I see occasionally, generally in school-girls. These recurrent sprains may manifest other features, as will be described under chronic sprains, but they can be guarded against by a simple device—namely, raising the outer side of the heel some three-sixteenths of an inch and sometimes "floating out the heel" in addition.

ENCOURAGEMENT OF FUNCTION

By this term I mean that early use of the affected limb should be allowed. In the example we are considering—inversion sprain of the ankle—the patient is allowed to put weight on the limb and need not lay up. He is encouraged to use the foot. This does not mean that he is told to go for a five-mile walk. I should not play a round of golf if I had recently sprained my ankle and it was painful, but with some support and the muscles

appropriately treated I should expect to be able to walk about and do my work from the first.

At this point we must recall what has been already said about the all-important part that muscle plays in controlling joint function, since we must concentrate on restoring muscle tone and encouraging the muscle to recover. Faradic stimulation—a method which has been described as graduated contraction—is of the greatest service. This method, as I have already stated more than once, I learned from Mr. Morton Smart in 1910, and I have used it and advised it continually since then. Essentially it consists in making muscle contract by an electrical stimulus, and both the degree and the rate of contraction are controlled by varying the stimulus. I will not enter into details of the treatment, but would emphasize its importance. Concurrently with electrical treatment massage is useful. This aids in the removal of swelling, mechanically getting rid of oedema, and improving the circulation. We generally combine electrical stimulation and massage; the one complements the other, even though the alternate contraction and relaxation, which is electrically controlled, produces what one may term auto-massage. Massage should never cause pain; it should be gentle and sedative in effect, and the small area, the site of maximum tenderness over the ruptured fibres, can be avoided.

Treated in this way, but depending on the degree of severity, a simple uncomplicated sprain should rapidly improve. The muscle quickly recovers tone, the torn structures unite, the swelling disappears, and the all-too-common sequence, the chronic sprain, is prevented.

Rotation Sprain of the Knee

There are sprains, however, which take a long time to clear up; they cannot be hurried. The commonest example is rotation sprain of the knee, such as is caused in a ski-ing accident. These severe sprains of the knee are often mistaken for torn and displaced semilunar cartilages, largely from the fact that a protective muscle spasm limits movement some 10 degrees short of full extension. The same principles should guide us in our treatment, and we must be confident of our diagnosis, for these sprains take many weeks, or even months, to recover. Unless we are familiar with this syndrome, and are true to our principles, we shall have difficulty in persuading the patient that the long period of partial incapacity is unavoidable, and forced movements or operation may be advised under a mistaken conception of the pathology.

Chronic Sprains

A simple sprain which is neglected or inefficiently treated may clear up if the injury is only trivial, but if the degree of damage is more severe symptoms will persist or will recur, and a condition that may be called a chronic sprain follow. The most common sequelae of sprains are: (1) persistent pain; (2) muscle atrophy; (3) limitation of joint movement; and (4) recurrent synovitis.

If the acute sprain be correctly treated these sequelae will be avoided. We must remember the importance of the time factor, which has been emphasized in considering the rotation sprain of the knee. The chronic sprain has supplied the main field of work for the bone-setter and the osteopath, and, to a large extent, continues to do so, both in this country and in America. One is often asked what the irregular practitioner accomplishes; what it is he really does when he claims that "he is putting a bone back in place." It is clear that unless we believe in the occult, there must be some fairly simple explanation, and it is not, I think, far to seek. He forces joint movement; he breaks down adhesions; and, if he is

successful, restores the normal range. Any medical man can do the same thing, as well or better. It is not essential to be ignorant of anatomy in order to be able to put a joint through its full range, although it is necessary to be ignorant of both anatomy and physiology if one is to say with conviction that a small bone is "out" in a wrist or an ankle which is the site of pain caused by adhesions.

The position was admirably summarized by Sir Robert Jones when, in his Cavendish Lecture, he said:

"Let me emphasize the statement that there is nothing which the manipulator does which cannot be more safely undertaken by any practitioner who possesses a knowledge of the pathology and elementary anatomy of the joints. Let it be fully realized that there are no hidden or mystic rites in the art of bone-setting."

Adhesions

The direct effect of the injury—the tearing of fibres in the ligament or joint capsule—is an outpouring of blood and lymph about the site of the tear, followed by organization of the clot, and the formation of fibrous tissue. The fibrous tissue may form a band anchoring certain folds in the capsule or preventing normal mobility of the joint. The diminution of range may be great, as shown commonly in a shoulder which is stiff as the result of enforced rest following a dislocation, or it may be small as in the inferior radio-ulnar joint or the wrist. When the patient uses such a joint and attempts to perform an ordinary everyday action, the result is pain and a feeling of weakness, or, in a weight-bearing joint, of insecurity, because of the pull on this adventitious band.

The differential diagnosis between a joint stiff as the result of inflammation and one stiff as the result of limiting adhesions is often easy but sometimes difficult. The most useful clinical test is one which we owe to Robert Jones, who used to teach that a joint stiff because of inflammation had limitation of movement in all directions, but that adhesions limited movement in certain directions only.

Adhesions limit movement very commonly, and may give rise to considerable pain and disability even when the excursion of the joint is almost, but not quite, full. It is not uncommon to see a patient complaining of disability of the knee, and on examination to make out full mobility, except that external rotation in flexion is just limited and gives rise to pain. Any gross loss of movement is easy to see, but we must bear in mind that very slight limitation caused by an adventitious band, an adhesion, may cripple the patient. Indeed, we may fail to make out any loss of movement, any diminution in the normal range, in a joint which fails to recover following injury. If we can exclude disease, inflammatory or neoplastic, and the skiagram is normal, it often repays us, empirically, to move such a joint through its full range under anaesthesia. With a clear history I should not hesitate to advise or practise manipulation, even though I could not be sure that movement was limited. One may well break down an adhesion in a joint in which the diminished range was too small to be detected with certainty on clinical examination.

The principles, then, on which we rely in undertaking the treatment of the chronic sprain are:

1. To overcome limitation of movement by forcing movement, either gradually by exercises and repeated forcible manipulation up to the patient's tolerance, or by forcible manipulation under anaesthesia.

2. To build up the musculature. It is true that active exercise is the greatest stimulus to the building up of muscle, but it is here again that the treatment by graduated faradic stimulation is of great service.

When one member of a group of muscles—for example, vastus internus—is markedly atrophied, there is no exercise that I know which rebuilds it, makes it catch up with the remaining members of the quadriceps group, so well as graduated exercise electrically provoked. The same is true in the adductor strains, caused by small tears in the muscle, the so-called “riders’ strain.” In the early stages it is far easier and the result is obtained more rapidly by this electrical method than by exercises. In the later stages of recovery active exercise against resistance supplements and then supplants the electrical method.

Technique of Breaking Down Adhesions

This technique, which has been given the grand name “manipulative surgery,” is easily acquired. The bonc-setter of the old days, who had to work without anaesthesia, developed a technique for overcoming the resistance of the antagonistic muscles and catching them off their guard. He combined rotation with the movements of flexion and extension. Hutton used to say: “The twist is the thing.” But the practitioner has no need to possess any superlative or supernatural skill. Under anaesthesia he can put any joint through its full range, and, remembering that the range differs in different individuals, he can always compare it with that of the sound joint of the opposite side. Experience is of value, as, indeed, it is in all treatment, but it is not beyond the power of the ordinary doctor to acquire a working knowledge of the technique.

After-Treatment

The necessary after-treatment is to keep the parts moving, to restore function, and to prevent the re-formation of the limiting bands. The treatment conforms to that advised for the acute sprain, but the co-operation of the patient is needed. He must be encouraged to try and use the joint, assisted by the masseuse. Faradic stimulation is again a most useful part of treatment; some of us consider it an essential part.

Chronic Sprains Complicated by Sepsis or Disordered Body Chemistry

It is a fact that sprains and allied injuries in the young adult or the adolescent tend to recover more quickly than similar injuries in later life. There is, then, a second factor to bear in mind besides the injury. If a sprain in a man of 40 fails to get well we should be on the look out for a predisposing cause—for example, sepsis or disordered metabolism. There may be some apical infection about the root of a dead tooth, a septic tonsil, or there may be some chronic constipation or failure of elimination which is playing a part.

The physician should bear this in mind and examine the patient, and not focus his attention only on the injured joint. The knee which will stand ordinary use but shows signs of irritation on over-use is an instance, and, although not truly to be classed as a chronic strain, becomes painful and remains painful as the result of active use, and the trouble not infrequently clears up on removal of the underlying cause.

Sprains of Muscle and Muscle Attachments

There are certain occupational injuries which are classed as chronic sprains. The so-called “tennis-elbow” is one; this is an example of the over-use of a muscle group, and some tearing or periostitis about the attachment of the tendon into its bony insertion. The tearing of fibres in the adductors of the thigh, either in the substance of the muscle or at its attachment to the pubic ramus—the so-called riders’ strain—and the tearing of fibres in the calf

of the leg—erroneously described as a ruptured plantaris, but in fact caused probably by the rupture of some of the deep fibres of the soleus—are others. It is worthy of mention that the plantaris tendon is usually found intact when we are called upon to operate for suture of a ruptured tendo Achillis, so that it is unlikely that it ruptures in the lesser injury. The detailed methods used in the treatment of these injuries of muscle will vary, but the same underlying principles will guide us in our efforts to restore function.

Conclusion

In conclusion, I would urge that these minor injuries should be given a rather more prominent place than they at present occupy in the teaching of the medical student. An effort is being made in certain directions and in some medical schools to improve the teaching on fractures, and it would be wise if we could improve our teaching on the handling of sprains and allied injuries of muscles and joints at the same time. I know how fully occupied the medical student is, how his time is taken up, and how intensive the course has become, but still I would urge that we must attend to his teaching in these simple injuries, and must insist on his having some idea of what is being done in the physical treatment departments. He does not need to be a skilled masseur, but he should know something of massage and its possibilities for good and harm that he may know when it is to be advised. He should at least see the electrical methods in use, that he may know what we are talking of when we speak of faradic stimulation of muscles. He should realize the value of a properly applied bandage; he should appreciate that a supporting bandage to assist in stabilizing a wrist should be put on round the joint itself, and not half-way up the forearm; and that for a sprained ankle the bandage must include the heel.

It is by attention, or lack of it, to diagnosis and treatment in these minor injuries that many reputations have been made or lost.

Nosokomeion is the official organ of the International Hospital Association, and is published quarterly by W. Kohlhammer of Stuttgart (annual subscription R.M. 12, plus postage). It is of special value to all who are interested in hospitals, and the international character of its contents allows a comparative view to be taken on all branches of hospital activities. The articles are printed in English, French, or German, and are individually summarized in each language. No. 1 for 1934 was a special number on the small hospital of 100 to 300 beds, and contained eleven articles, of which the following are representative: G. von Deschwanden, “Was muss der leitende Arzt eines mittelgrossen Krankenhauses wissen?”; Raphael Jackson, “The Possibilities for Administration, Management, and Accounting of the Smaller and Rural Hospitals”; Ernst Balser, “The Small Hospital of the Future capable of being Enlarged”; Gustav Birch-Lindgren, “Some Points of View on Small Hospitals”; and Marcel Labbé, “L’Organisation du Service de Diététique dans un Hôpital de 300 Lits.” No. 2 contained the programme of the Fourth International Hospital Congress, to be held in Rome in May, 1935, and reports from national hospital associations and representatives of twelve nations. Other interesting articles were: B. Albert, “Fehler im Krankenhausbau” and E. M. Bluestone, “On Medical Organization in Hospitals.” No. 3 contains eleven papers from this year’s international post-graduate course on hospital technique, including: P. Manz, “Organisation, Technik und Einrichtung im Krankenhaus”; A. Rollier, “L’Organisation de la Cure de Travail dans la Clinique manufacture internationale de Laysin”; and Letitia Fairfield, “Ante-natal Care and Hospitals.”

PATHOLOGY AND TREATMENT OF SPRAINS*

BY

SIR MORTON SMART, K.C.V.O., D.S.O., M.D.

LATE MEDICAL OFFICER IN CHARGE ELECTRICAL DEPARTMENT,
HOSPITAL FOR SICK CHILDREN

As if it is customary to use the words strain and sprain somewhat indiscriminately, I would suggest that the word "strain" be used to denote injury to the muscle component of a joint, resulting from excessive stress, and "sprain" to denote injury to other structures of a joint as well as its muscles. A strain, therefore, may be defined as the state of a muscle the tissues of which have suffered damage because the normal strength of that muscle has not been sufficient to resist the stretching effect of the force at the moment of its application or because the fibres of the muscle have been taken unawares before they have had time to reach full contraction to resist the stress. A sprain may be defined as the state of a joint any of the structures of which, besides the muscles, have been injured as the result of a force applied to it. When the degree of violence is such that a muscle's power of contraction is overcome, the joint elements may sustain damage of varying degree; when the damage is limited to the muscle tissue alone a strain is produced, but when it extends to one or more of the component parts of a joint, other than the muscle, a sprain results.

How an Acute Sprain Is Caused

In considering injuries to joints which produce sprains certain mechanical features should be borne in mind. So far as the protection of a joint is concerned, there is an instinctive vigilance on the part of the muscles, and this constitutes a joint's first line of defence. The other structures of the joint cannot be injured unless this line of defence gives way from: (1) the stress applied to the muscles protecting the joint being powerful enough to overcome their power of resistance; (2) the muscles having been taken unawares at the moment of the application of the stress; (3) fatigue having slowed up the normal rate of the muscle's contractility; (4) loss of tone from previous injury or disease limiting the capacity of the muscles for quick reaction to a sudden increase in their tension.

In this way an acute sprain is produced, the effects of which and the time necessary for recovery vary in accordance with the extent of the injury to the tissues and the particular structures damaged. In cases in which the brunt of the strain and the main damage are chiefly referable to the muscles and the injury to other joint structures is only slight, the sprain may be looked upon justifiably as a slight acute one. While this is true, however, the result of the injury may not be so slight as it seems, and the condition is all too frequently neglected by the patient as regards treatment. This slight sprain may become serious, because the muscles lose their tone and undergo a varying amount of wasting, and the consequent loss of efficiency, which becomes greater as time goes on, ends in the joint becoming less able to perform its function efficiently and quickly, and therefore liable to further injury from causes which would be quite harmless were the muscles in their normal alert state.

In the severe forms of acute sprain one structure of a joint may suffer to a greater extent than others, but all may become affected to a more or less degree, either at the moment of the accident or following on the changes consequent to repair, so that structures not directly

affected at the time of the accident frequently become seriously implicated later.

To visualize clearly the possible results of an excessive stress applied to a joint it is worth recalling the main functions of each structure. The bones are mainly supporting, and are the levers upon which the muscles act; the ligaments aid in holding the ends of the bones together and limit their range of movement. The synovial membrane, by its secretion, helps to lessen the friction of movement and renders movement smooth; the cartilage lining the ends of the bones acts as a shock absorber.

Functional Importance of the Areolar Tissue

Filling up the interspaces round all the other structures, and carrying the arteries, arterioles, capillaries, veins, lymphatics, and nerves, is a most important joint structure—namely, the delicate areolar connective tissue. Damage to this tissue and its contained important structures is, owing to its situation and delicate nature, of frequent occurrence, and in my opinion is one of the main causes of continued loss of function of a joint after even a most trifling injury, and particularly when such injury is treated by prolonged rest. It is a somewhat soft substance possessing normally great tenacity and elasticity, and abundantly distributed throughout the body; by reason of the intercommunication of the areolar spaces effusion into this tissue is capable of travelling a long way from the seat of injury.

Areolar tissue, with its contained important structures, everywhere fills up crevices and spaces in the joints, and acts as padding between muscle groups and muscle fibres; in situations where free and easy movements are required the fibres of the supporting areolar tissue are loosely arranged; and where firm binding of parts together is necessary the fibres are densely arranged. Areolar tissue normally contains a small quantity of a translucent lymph-like fluid, sufficient to keep it moist and supple, and I suggest that the absence or diminution of this fluid, as may happen after injury, may be one of the contributory causes of the characteristic creaking sensation which takes place on movement of joints in the later stages of trauma.

By its normal moistness and suppleness and by its tenacity and elasticity areolar tissue is enabled to accommodate itself easily to the widest range of movements of the joint. When areolar tissue becomes soaked in lymph which has become stagnant after injury, unless this lymph is quickly removed it undergoes hardening changes leading to organization and adhesions, and its response to movement becomes inflexible and less pliable, resulting in a feeling of stiffness in the joint. In course of time this is followed by adaptive shortening of muscles controlling the joint, owing to similar loss of pliability and elasticity in the connective tissue of the muscle sheaths.

An important factor, therefore, producing chronic stiffness of injured joints, even after slight sprains when there is no very evident structural damage and no demonstrable adhesions, is the malnutrition of the areolar tissue due to interstitial oedema. The condition is really the outcome of imperfect repair, and is one of the most prolific causes of persistent discomfort and dysfunction in joints; it is very largely contributed to by over-rest.

Rest in the Treatment of Sprains

The advocacy of rest as the principal treatment of sprained joints almost certainly originated from the natural tendency of the possessor of a sprained joint volitionally to place that joint in the position of greatest ease, and on this fact the principle that pain is Nature's cry for rest is based. But the direct result of trauma and the processes leading to repair is a great increase of internal pressure in the surrounding tissues, due to bleeding and pouring out of

* Read in opening a discussion in the Section of Orthopaedics at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

lymph, so that there is stretching and pressure on the tissues, particularly the nerve endings, and pain in injury is quite unavoidable. Pain, therefore, may be more truly described as the "cry of the injured tissues for active help." Limitation of movement of an injured joint is also encouraged by the increase of pain, which is due to the contracting muscles further increasing tension between the tissues, and it is this close association of pain and movement which, in the belief that the prevention of pain is essential to repair, produced the theory that all movement must be prevented. Hence treatment by rest became the recognized method.

The treatment by rest is only palliative, as it certainly relieves pain, but surely this is a small matter when the disastrous consequences are realized. Rest tends to diminish circulation; absorption is not sufficiently stimulated, and the various structures become stretched by the long-continued tension. They remain relaxed for a long time, and, when organization follows, muscles, tendons, and areolar tissue become matted together, causing varying degrees of stiffness and limitation of movement. Circulation of the blood and lymph becomes further interfered with by compression of the blood and lymph vessels, due to intercellular tension. Muscular wasting from disuse and other causes takes place rapidly after injury, and so further complicates joint activity.

When a joint has been injured, no matter to what degree the structures are damaged, the keynote of recovery is the rate of absorption of effusion and the completeness of the absorption, and it is mainly upon these two factors that the question of the ultimate sequel to the injury depends. Incomplete recovery causes a degree of impairment, which may extend from a feeling of slight weakness in the joint and a sensation of untrustworthiness to limitation of movements to any extent. Even if the result of an injury falls mainly on one structure of a joint, prolonged rest may cause any or all of the other structures to become affected. It is chiefly from this fact that even a slight sprain, if rested for too long a period, may develop into a serious injury likely to produce secondary complications, which, for a long time and even permanently, may interfere with the perfect function of the joint.

The Value of Muscle Action

As rest physiologically tends to reduce the rate and amount of circulating blood and lymph through any part, while, on the other hand, the physiological changes called into play by muscular action promote a very active circulation of blood and lymph, not only to the muscles themselves, but to all the neighbouring tissues, I submit that muscle action, as a means of assisting the natural processes of repair after injury, has not received the attention it deserves. Muscle is a highly sensitive structure, with power instantly to respond to a variety of stimuli when in a state of health; when for any reason it loses its tone wasting follows rapidly. The loss of tone and the loss of power fully and rapidly to contract is of obvious importance to the security of a joint, and no joint can be considered to have recovered completely from injury to any of its structures until the tone and contractility of its musculature have been successfully restored to normal.

Although the restoration of muscle function is of such importance the muscle condition passes too often almost unnoticed, in spite of the fact that a joint may be crippled for long periods owing to the faulty nutrition of the other structures as the immediate result of atrophy of muscles and the mechanical disability. Even when a muscle is not obviously wasted, loss of tone alone produces a partial loss of function, and it becomes incapable of full contraction, its time rate of contraction becomes slower, and its efficiency to act synchronously with others in group action

is diminished; thus the joint upon which it acts has its balanced action altered and the nutrition of its structures interfered with. The muscles which oppose wasted ones also suffer and further upset the balance of the joint because of the loss of the normal pull of the wasted and atonic muscles, and in time they become shortened from contraction of their fibres and interstitial tissue.

The interference with "muscle sense" which occurs when muscles are wasted upsets the power of the latter to carry out co-ordinated movements, and in consequence joint structures have to submit to harmful stresses, which would normally be countered by muscles in a state of fitness.

Such imperfect recovery of muscles following sprains of joints is so often met with that it would appear to be due to a general misunderstanding of the importance of the muscle changes, and a want of comprehension of the serious late results of these changes on the other structures of the joint if repair and full recovery of muscle function are delayed or incomplete. As a consequence of these muscle changes many chronic sprained joints, particularly of the knee and shoulder, come to be looked upon by the patient as the natural end-result of an injury and to be expected, whereas the disability, which may be slight or serious, is due to mechanical unbalance, and is easily curable.

The physical and chemical phenomena coincident with the normal activity of muscles are essential to their efficiency and sensation of well-being, and to maintain muscle in a healthy state the regular normal fulfilment of the functions of the arterial, venous, and lymphatic circulations is essential; this is even more so when tissues are injured. The benefit derived from the physiological changes consequent on painless muscular action, produced either naturally or by the correct type of electrical stimulation, cannot be too strongly stressed, and if painless muscular movements are instituted as soon as possible after a sprain the distressing complications leading to a chronic sprained joint with all its pain and disability can be prevented.

Effects of Treatment by Muscle Stimulation

Briefly summarized the effects of the treatment of injured muscles and joints by correct electrical muscle stimulation, which produces graduated and controlled contractions and relaxation, are:

1. Muscle elasticity, irritability, contractility, and tonicity are rapidly restored to normal.
2. A great increase of blood to the muscles and to the neighbouring tissues is produced, with all the attendant beneficial consequences.
3. Waste tissue products are rapidly cleared away and stagnation of lymph, with all its serious sequelae, is prevented.
4. A large supply of oxygen and nourishment is brought to the damaged part.
5. Rapid absorption of fluid and extravasated blood is actively promoted.
6. Beneficial chemical and physical changes following muscle activity take place.
7. The movements of muscles and tendons do not allow organization of lymph between their surfaces, and adhesions are thus prevented.
8. As the movements prevent stagnation of lymph in the areolar tissue in the joint interspaces, the danger of the areolar tissue losing its suppleness, pliability, and flexibility is diminished.
9. If, in later stages, adhesions have formed, the adherent surfaces are gently but effectively torn apart, by causing increasingly powerful contractions of the muscles separately.
10. Muscles are prevented from losing their tone and from wasting, muscles already wasted increase in bulk.

It should be noted that a recently injured and painful muscle can still be made to contract and relax, and the

degree of the contractions and relaxations can be so controlled that the origin and insertion of the muscle need not be approximated until desired; consequently, the beneficial physiological changes called into activity by muscle action are produced with the minimal amount of strain of its fibres, and the movements of the injured joint as a whole can be kept within minimal range. If treatment is based on these principles no uncomplicated acute sprain should become a chronic one.

ARSENIC IN ITS RELATION TO THE KERATIN TISSUES

BY

SYDNEY SMITH, M.D., F.R.C.P.Ed., D.P.H.

REGIUS PROFESSOR OF FORENSIC MEDICINE, UNIVERSITY OF EDINBURGH

AND

E. B. HENDRY, B.Sc.

DEPARTMENT OF FORENSIC MEDICINE, UNIVERSITY OF EDINBURGH

The keratin tissues, hair, nails, and skin, are of considerable importance in connexion with arsenic poisoning from a physiological as well as from a medico-legal point of view. In many of the published cases the presence and distribution of arsenic in these tissues has been of major significance in the investigation, and it seemed worth while, therefore, to obtain further experimental information on certain points concerning the effects of arsenic on the keratin tissues.

It is obvious that a knowledge of the mechanism of arsenic fixation in hair may give an important insight into the body's defence against the poison, and that examination of hair in certain cases of arsenical poisoning may be expected to yield information of great value. From the medico-legal aspect it would seem that the finding of arsenic in the hair would be strong evidence of its administration; but before the analyses may be so interpreted it is necessary to inquire into a number of other possibilities. For example, is it possible for hair to absorb arsenic from fluid bathing the shaft; or does any arsenic present necessarily come from the body fluids bathing the hair root? The importance of such a question may be illustrated by reference to one or two cases.

In the Seddon case the victim died about fourteen days after the first dose of arsenic, and this element was found not only in the proximal parts (3 mg. per 100 grams hair), but also in the distal parts of the hair (2 mg. per 100 grams hair), which was about twelve inches long. The presence of arsenic in the distal three inches raised the presumption that arsenic had been administered more than a year before death. Willcox suggested, however, that the arsenic in the distal ends might have been absorbed from the blood-stained body fluid which had come into contact with the hair, and by *in vitro* experiment proved that this explanation was possible. *Per contra*, in the Hearn case, the presence of arsenic in the hair of Miss Everard was interpreted as indicating the administration of arsenic over a considerable period, whereas it may well have been due to contamination from water which had soaked into the coffin after percolation through the arsenic-containing soil. Thus from similar facts we have opposite deductions made on behalf of the Crown, and both to the disadvantage of the accused.

It is well known that arsenic may be found in the hair after all traces of it have disappeared from other organs of the body, but it is desirable to ascertain whether the quantity found indicates a preferential absorption of

arsenic by the keratin tissues or merely a trapping of arsenic in the non-vascular tissues. It seems further of interest to ascertain whether, if there is preferential absorption, it is a function of living pre-keratin tissues or whether keratin itself absorbs arsenic preferentially *in vitro*. It is also desirable to know if this absorption is due to chemical combination between arsenic and certain products of cellular activity, or if it is a case of simple absorption. Other problems include those of ascertaining whether or not arsenic can travel along the hair shaft; whether it is possible to ascertain from the distribution of the poison if it has been absorbed from the body or if it has resulted from external contamination; and whether any inferences of value can be drawn from the amount and distribution of arsenic as to the time when a dose of arsenic was administered, and the size of the dose. We are still able to answer very few of these questions, and the present paper must be looked upon as a preliminary report.

Preferential Absorption

If we consider the results of a series of cases dealt with in the report of the Royal Commission on Arsenic Poisoning (1904) we find that the keratin tissues do take up more arsenic, weight for weight, than the other tissues of the body. For example, a number of individuals were given 5 mg. of arsenic per day for two months; on examination the hair of these men was found to contain from 2 to 5 mg. of arsenic per 100 grams of hair. The total quantity of arsenic taken by each individual was approximately 300 mg., and if this amount, without allowing for excretion (which would account for the greater part of it), be supposed to be equally distributed over the body the concentration would be about 0.5 mg. per 100 grams of body weight—that is, about one-tenth of the quantity actually found in the hair. Similar figures can be shown for the nails and to a lesser extent for the skin.

(A) BY HAIR REMOVED FROM THE BODY

It is known, as has been mentioned, that hair soaked in an arsenical solution absorbs arsenic, but it is evidently desirable to place this observation on a quantitative basis and to ascertain whether, under such conditions, the hair can attain to, or surpass, the concentration of arsenic in the surrounding fluid. For this purpose a series of tubes were set up each containing 0.5 gram of hair or nail clippings and 10 c.cm. of a solution of sodium arsenite containing 0.01 mg. of arsenic per c.cm. The liquid was decanted from each at definite intervals, and an aliquot was analysed by the Marsh process. The hair in each case was removed and washed with six portions of water, and allowed to drain thoroughly after each washing. The organic matter was destroyed by the method of Wood-Smith¹ of boiling with equal parts of concentrated nitric and concentrated sulphuric acids. After complete removal of nitric acid the liquid was made up to a known volume, of which an aliquot was boiled with 0.5 gram of potassium metabisulphite to remove the last traces of nitric acid and reduce arsenate to arsenite. Arsenic was then determined by the electrolytic Marsh apparatus. The results of one typical experiment of the series are shown in Table I, where the density of human hair is taken as unity. Since, however, part of the absorbed arsenic might conceivably be due to swelling of the hair, a known weight of hair (0.3036 gram) was allowed to soak in water for seventy-two hours; at the end of this time it was removed and dried as thoroughly as possible with filter paper in the same way as the arsenic-containing hair (it still felt damp to the touch). The increase in weight was 0.0221 gram, or 7.3 per cent. When this hair was allowed to stand in

the balance case for half an hour the increase fell to 0.0040 gram, or 1.3 per cent. In other words, there was no simple imbibition of the fluid surrounding the hair, and the figures of Table I represent a true absorption of arsenic.

TABLE I

Length of Time of Soaking	Concentration of Arsenic in the Hair	Concentration of Arsenic Left in the Solution	Percentage of Arsenic Recovered
	mg. per c.cm.	mg. per c.cm.	
0 hours	0.00	0.010	
20 "	0.024	0.009	102
44 "	0.03	0.008	95
118 "	0.05	0.007	95
145 "	0.05	0.008	105
234 "	0.05	0.007	95

It is to be observed that the hair absorbs arsenic in increasing amounts, gradually attaining a concentration of arsenic about seven times that of the surrounding solution. Evidently, too, the final concentration is greater than the usual figure hitherto reported; it is unaltered by increasing the time of soaking above seventy-two hours; and generally, it is not increased when the hair is soaked in a stronger solution of arsenite. In the cases given in the Royal Commission Report, the level of arsenic in the hair runs fairly uniformly at about 2 to 3 mg. per 100 grams hair, not only in those cases where small doses have been given over a long period but also in those where the hair has been examined long periods after a single dose.

In all the published cases of arsenic poisoning in which the hair has been analysed the level of arsenic concentration runs about the same figure. (Table II.)

(B) BY NAILS REMOVED FROM THE BODY

In the case of nails the original weight of 0.330 gram increased by 38.2 per cent. after 144 hours' soaking. After standing three hours in the balance case, this increase

was reduced to 17.6 per cent. Before soaking in arsenic solution the nails were scraped as free as possible from adhering skin, and before analysis the liquid was removed by filtration and thorough washing with distilled water. Results obtained are shown in Table III, where the density of human nail is taken to be 1.2. The last column represents the concentration of arsenic in the nails corrected for uptake of the medium on the assumption that 0.5 gram of nail takes up 0.19 c.cm. of the solution (that is, 0.0019 mg. of arsenic and 38 per cent. of its volume of the solution).

TABLE III

Length of Time of Soaking	Concentration of Arsenic in the Nails	Concentration of Arsenic left in the Solution	Percentage of Arsenic Recovered	Concentration of Arsenic in the Nails (corr.)
	mg. per c.cm.	mg. per c.cm.		mg. per c.cm.

67 "	0.084	0.007	105	0.079
93 "	0.084	0.006	95	0.079
116 "	0.107	0.007	115	0.103
188 "	0.192	0.0018	98	0.185

It is a remarkable fact that nails in arsenical solution can take up arsenic to a concentration of about 100 times the final concentration of the surrounding solution, and in our experiments had not even then reached the maximum.

Evidently both nails and hair removed from the body and soaked in a solution containing arsenic (as sodium arsenite) can absorb that element until the concentration is far in excess of that of the surrounding medium. In other words, they exhibit preferential absorption. That this absorption is not merely a case of surface adsorption is shown by the fact that when hair is soaked in sodium arsenite solution, as in the above experiments, none of the arsenic is removed by thorough washing with dilute caustic soda before analysis. The importance of this observation can hardly be exaggerated, for it has been customary to consider a higher concentration of arsenic in the keratin tissues than in the viscera as proof that the arsenic was absorbed by those tissues during life; that assumption is proved to be false.

Absorption from the Living Body

Under the conditions of our experiments the arsenic is evenly distributed along the length of the hair, but if arsenic is being absorbed into growing hair or nails from living body fluids, a different distribution is to be expected. At first arsenic should be found only in the proximal end. As the hair grows either an arsenic-containing band grows with it (in the case of the poison being administered over a short period) and is followed by an arsenic-free proximal zone, or, in the case of long-continued administration or continued presence of arsenic in the blood owing to slow excretion, more and more of the hair contains arsenic until, eventually, through cutting or falling, the distribution becomes uniform.

In the majority of cases of poisoning one would expect to find more arsenic in the proximal end of the hair than in the distal, but, of course, for a variety of reasons, this distribution is not absolute. For one thing, the relative lengths of the arsenic-containing and arsenic-free parts will vary from case to case with the time of administration of the poison, the rate and amount of excretion in the vomitus, urine, and faeces, the rate of growth of the hair, and the time and frequency of hair-cutting. Moreover, as Willcox has pointed out, "sweat and sebaceous secretion contain arsenic, and as the whole length of the hair comes in contact with these secretions, the limitation of arsenic to the proximal portions of the hair is relative.

not absolute." However, in cases of absorption *in vivo* some such distribution may generally be expected, and the finding of more arsenic in the proximal parts than in the distal is strong evidence that the arsenic has been absorbed from body fluids—provided it can be shown that no external contamination can account for it. The expectation of a non-uniform distribution of arsenic in hair is in any case dependent on the supposition that the arsenic, once absorbed into the hair, remains fixed and can neither travel along the shaft nor be reabsorbed by the body, and experiments to justify this supposition have hitherto been lacking.

Methods of Absorption Determined

The following experiments were carried out *in vitro* to determine whether or not arsenic is capable of travelling along a hair fibre. A lock of human hair about 10 cm. long was placed so that the cut ends dipped to the extent of about 4 cm. into a solution of sodium arsenite containing 0.1 mg. of arsenic per c.cm. This solution was contained in a test tube and the hair was arranged round a tightly fitting cork so that 5 cm. of it was completely out of contact with the fluid. Within twenty-four hours it was observed that the hair above the stopper was damp for a length of 2 cm. It was allowed to stand thus for three weeks, and at the end of that period the hair projecting above the stopper was divided into five sections, and these were analysed without previous washing. The results of the analyses are shown in Table IV.

TABLE IV

Weight of the Section	Total Amount of Arsenic Present	Notes
0.144 gram	0.5 mg.	Section nearest the solution. Very wet
0.122 "	0.15 mg.	Hair damp
0.101 "	Trace	Slightly moist in one part
0.100 "	Nil	Hair quite dry
0.067 "	Nil	Section farthest from the solution. Dry

Two important points emerge from these results. First, the hair not immersed in the liquid but wetted with it by capillary action actually contains more arsenic than the hair in contact with the solution. This is due to evaporation of the arsenical fluid on the hair fibre. Secondly, local contamination at the proximal end has resulted in that gradual distribution which is to be expected if absorption takes place from the body fluids. But it is evident that it may equally occur after death if by any chance the hair is soaked in an arsenical solution at the proximal end only.

In order to prevent the solution travelling up the outside of the fibre, the experiments were repeated with a thin layer of paraffin wax laid round the top of the cork. The hair was allowed to stand for three weeks in a solution containing 0.1 mg. of arsenic per c.cm. No moisture was visible outside the tube and the volume of the solution did not apparently diminish; 3 cm. of the hair (weighing 0.164 gram) nearest the liquid contained no arsenic.

The experiments indicate beyond doubt that local wetting of the hair shaft with arsenite solution causes arsenic to be absorbed over a length of hair by "creeping" of the solution and absorption from outside. They show equally definitely that travel of the arsenic along the inside of the fibres does not take place; and that, therefore, the graduated distribution of arsenic is legitimately to be attributed to *in vivo* absorption only if contamination from some external liquid source can definitely be excluded.

Reabsorption by the Body

They also suggest that arsenic once deposited in hair or nails is finally lost to the body—a suggestion which is *a priori* indicated by the fact that hair shafts, the keratin layers of epidermis, and so on, are really dead tissues, and are, indeed, excretions. However, there appears to be a division of opinion on the subject, for whereas Willcox states that "it is probable that during the prolonged administration of arsenic a certain amount becomes deposited in the skin, hair, and nails, and this is gradually reabsorbed, being excreted by the urine and faeces," Althausen and Gunther,² on the basis of a study of excretion of arsenic before and after treatment with sodium thiosulphate, have shown that arsenic is not reabsorbed from the hair.

In our early experiments the fact that we were able to rinse arsenic-soaked hair several times with water and even with dilute caustic soda without appreciable loss of arsenic suggested that reabsorption of arsenic from hair to the living body was at any rate a slow and difficult process. Quantitative experiments on this point, however, showed that arsenic-soaked hair containing the maximum of 5 mg. per 100 grams could lose part of the arsenic after prolonged soaking in distilled water. After fifteen days' soaking in this manner, the water being changed every twenty-four hours, about 40 per cent. of the arsenic had been removed. Further soaking would not remove the other 60 per cent. Furthermore, it was found that the arsenic could not be removed to any appreciable extent from the hair of a person who had been receiving arsenical injections. This suggests a method of differentiating between arsenic absorbed *in vivo* and arsenic derived from some external source of contamination.

Summary

It has been shown that keratin tissues when soaked in arsenical solution exhibit the phenomenon of preferential absorption. The arsenic so absorbed can be partly removed by very prolonged soaking in distilled water, but rapid rinsing either with water or dilute alkali does not affect the arsenic content in any marked degree. By this method the maximum arsenic content of hair is found to be 5 mg. per 100 grams, and much higher values can be obtained in the case of nails. *In vitro* experiments have shown that arsenic can travel along a hair fibre only if "creeping" of the solution along the outside of the hair be possible. It has been demonstrated that arsenic absorbed into hair *in vivo* cannot be removed by prolonged soaking, and this fact is tentatively put forward as a basis for a method of distinguishing between arsenic absorbed *in vivo* and arsenic resulting from external contamination.

The expenses of the work were partly defrayed by a grant from the Moray Fund of this University.

The *Transactions of the Twentieth Annual Conference of the National Association for the Prevention of Tuberculosis* have now been published. This conference was held last June, and was reported at the time in these columns. It was largely concerned with reviewing the progress made in the twenty-one years of the life of the National Association, and this volume of *Transactions* has consequently a definite historical interest. The National tuberculosis scheme is discussed from various points of view, and a comprehensive survey of the present position is thus given. The main trends in further development are indicated.

FATAL PERFORATION OF THE CAECUM
IN A CASE OF SPRUE

BY

G. CARMICHAEL LOW, M.D., F.R.C.P.

SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES; DIRECTOR,
DIVISION OF CLINICAL TROPICAL MEDICINE, LONDON SCHOOL
OF HYGIENE AND TROPICAL MEDICINE

AND

N. HAMILTON FAIRLEY, M.D., D.Sc., F.R.C.P.

ASSISTANT PHYSICIAN AND DIRECTOR OF PATHOLOGY, HOSPITAL FOR
TROPICAL DISEASES; LECTURER IN APPLIED PATHOLOGY,
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

Cases of perforation of the intestine in sprue are extremely rare, and those so far reported have been associated with ulcers in the small bowel. Faber (1904) reported a case of death from peritonitis following rupture of an ulcer in the small intestine. At necropsy sixteen small ulcers were found at various parts of the lesser bowel, but the large intestine was free. Fischer and von Hecker (1922) reported several small ulcers in the lower jejunum and ileum, and Mackie and Fairley (1929) described a superficial healing ulcer in one of their cases about half an inch in diameter, located two inches above the ileo-caecal valve. In two cases reported by Manson - Bahr (1924) perforation had occurred. One of these—a case of ten months' duration—showed a large ulcer in the ileum six feet from the ileo-caecal valve opposite the mesenteric attachment; it measured one inch in diameter, and had perforated in two places, producing a fatal peritonitis. In the other case twelve ulcers varying in size from 0.5 to 1 c.cm. were found in the ileum, the mucosa of which was acutely inflamed. One small ulcer 3 mm. in diameter was found in the upper part of the jejunum; multiple perforations had resulted in peritonitis and death. The present case is of special interest because no evidence of ulcers in the small or large bowel was found at necropsy, and the perforation involved the caecum. An epitomized history is recorded below.

Case Record

Mrs. S., aged 58 years, was admitted to the Hospital for Tropical Diseases on February 28th, 1934, seriously ill with tropical sprue.

Past History.—Born in England, she had gone to India in 1900, and had remained there until 1926, since when she had not been out of this country. There was a history of malaria in 1901, and of dysentery, without recurrence, in 1902.

Recent History.—The onset of the immediate trouble occurred in September, 1925, when the patient began to have large, pale, frothy stools and flatulence, having lost much weight. These symptoms persisted, and she returned to England in March, 1925. The tongue was then sore with ulcers and fissures, and intestinal symptoms were marked. In 1927 she received three months' treatment with milk diet and temporarily improved. Then in November, 1930, she became definitely worse, receiving treatment including injections of liver extract over a period of six months without any great

benefit; subsequently she returned home, improving up to a certain point. By June, 1933, she had begun to lose weight; the stools were bad, flatulence marked, and the tongue sore; in July an anal fissure developed. Since Christmas vomiting occurred infrequently and she had lost 3 stone 9 lb. in weight. Attacks of tetany had also been present for a considerable period, the last being about a fortnight before admission. The stools were pale, sometimes formed and sometimes fluid; flatulence was severe, and she could not retain solid food, vomiting it almost immediately.

Physical Examination (February 28th).—Inspection revealed a thin, elderly, much emaciated woman with pale mucous membranes and conjunctivae. She was edentulous; the tongue was smooth and pale with hyperaemic edges. She was very weak on admission, and a grave prognosis was given. There was an apical systolic murmur, but no cardiac enlargement, and the breath sounds, though harsh, were normal. Abdominal distension was present, the muscles were atonic and wasted, and peristaltic movements were visible through the thinned abdominal parietes. Some tenderness was noted on deep pressure over the appendix area. An anal fissure was found on the posterior aspect of the sphincter, and above this the rectum felt ballooned.

Laboratory Records

(March 1st).—Red blood counts, 1,700,000 per c.mm.; haemoglobin, 50 per cent. (Haldane); colour index, 1.3; average diameter of corpuscle, 8.6 μ (halometer). The blood 'picture' was typical of megalocytic anaemia; megalocytes were numerous; anisocytosis and poikilocytosis were marked; normoblasts were scanty. Biochemical examinations were postponed until March 5th, when the serum calcium was 8.7 mg. per 100 c.cm., the

serum phosphorus 2.5 mg. per 100 c.cm.; and the glucose tolerance curve showed a maximal rise of 54 mg. per 100 c.cm. one and a half hours after the administration of 50 grams of glucose.

Progress Notes.—The case ran an apyrexial course with normal pulse rate and respirations until the terminal crisis with sudden perforation and peritonitis. A high protein, low fat, low carbohydrate dietary in the form of "sprual" introduced by Fairley in 1932 was used, and initially three injections of campolon (each 6 c.cm.) were given; a sub-maximal reticulocytosis of 10.4 per cent. (see Graph) occurred on the sixth day, and subsequently fluctuations in the counts occurred throughout the course of the disease, the percentage, however, always remaining above the normal. Though there was improvement in the alimentary features of the case, looseness of the bowels persisted, and there was but little gain in weight; though the red corpuscles showed some increase in numbers the haemoglobin percentage remained stationary (see Graph). Analysis of the stools on March 16th showed: total fat, 19.2 per cent.; neutral fat, 2.6 per cent.; fatty acids, 16.6 per cent.

On March 19th the patient was put on two tubes of "exhepa" daily (equivalent to $\frac{1}{2}$ whole liver), and this later was increased; daily injections of campolon (2 c.cm.) were also given, as indicated in the Graph. Again an appreciable increase in the red cells occurred, but the haemoglobin showed no improvement. A convalescent mixed diet was allowed on April 9th, and though the patient was troubled with flatulence she put on 2 lb. in weight, and progressed satisfactorily during the next week. The red cells also increased, and on April 16th the count showed red blood cells, 3,585,000 per c.mm.; haemoglobin, 50 per cent., colour index, 0.7; average diameter of corpuscle, 8 μ ; megalocytes, microcytes, anisocytosis, and poikilocytosis still present.

Haematological response in a case of tropical sprue dying from perforation of the caecum with peritonitis.

On April 18th, at 5.15 p.m., the patient complained of a sudden severe abdominal pain, and vomited copiously. She was in great pain, lying with the knees drawn up, and exhibited a greyish pallor and drawn facies. The abdomen was very distended, definitely rigid, and pressure increased the pain. Perforation with peritonitis was diagnosed, and Mr. A. H. McIndoe did an immediate laparotomy.

Operation.—There was a gush of gas and faecal fluid when the peritoneum was incised, a diffuse generalized peritonitis with ileus being found. A small circular hole about 1.5 cm. in diameter was found posteriorly, situated at the junction of a mobile caecum and ascending colon some two and a half inches above the base of the appendix. The bowel wall was very thin in the vicinity, but no ulcer or growth was palpated.

Necropsy.—The caecum and adjacent ascending colon were distended and thinned, and a circular hole was found in the bowel as indicated above. There was no induration or thickening around the perforation, and no signs of surrounding inflammation suggesting that perforation had occurred at the site of a former ulcer. A vein draining the area was thrombosed. Further details of the necropsy will be published separately later.

Comment

Though the patient had definitely improved as a result of treatment and the red corpuscles had increased by 1,885,000 per c.mm., the haemoglobin failed to increase in the way the vast majority of sprue cases do. The patient, as already stated, was very weak on admission, and it appears probable that venous thrombosis in a thinned and over-distended bowel led to sudden bursting of a devitalized area of the caecal wall. In the light of subsequent happenings it would probably have been better if the convalescent diet had been of higher protein and lower carbohydrate composition. Iron therapy was withheld for fear of irritating the bowel and increasing the diarrhoea.

The Christchurch Hospital, New Zealand, publishes a review of the work of the radium and deep therapy departments between 1924 and 1934, which has been compiled by Dr. P. Clennell Fenwick, F.R.C.S.Ed., who is in charge of the departments in question. In his introductory note he states that "during the last nine years every request for additional equipment has been granted at once, and we are now so well equipped that we are able to carry out the same methods of treatment that are in use in Europe and in America." In May, 1930, a special consultation clinic was organized, which meets weekly and is composed of all members of the honorary and departmental staff. Each patient is examined by the members, and re-examinations are made at regular intervals. Carefully worked out recording and "follow-up" systems are in routine use. The consultation clinic has been found to be especially useful in the case of persons who ask for examination under the impression that they have cancer; and the united assurance of an expert committee that such is not the case has done much not only to render the persons happier but to encourage people to come for advice. Since 1930 the clinic has examined 785 new patients, while the total attendances for examination and re-examination have been 2,004. Brief descriptions are given of the methods of treatment employed, together with summaries of the results obtained. There are also useful notes of the after-care of cancer patients and upon the mental aspect in carcinoma. A useful series of precautions to be observed in treatment appears at the close of the report.

Clinical Memoranda

TORSION OF HYDATID OF MORGAGNI SIMULATING ACUTE APPENDICITIS

The following case seems to merit report as illustrating one of the more uncommon conditions which may present the clinical picture of acute appendicitis.

A well-developed girl of 16 years was seen about five hours after the onset of abdominal pain, at first generalized, but later localized in the right iliac fossa, accompanied by vomiting. Temperature, 99°; pulse, 96. There was diminution of abdominal movement, some rigidity in the lower right quadrant, and tenderness just below McBurney's point. A fairly definite diagnosis of acute appendicitis was made. An hour later the abdomen was opened by Davis's incision: a considerable amount of sero-sanguineous fluid escaped from the abdomen. The appendix, which showed injection of its peritoneal coat, was removed. As the condition of the appendix seemed incompatible with such an amount of bloody fluid the pelvis was explored. The right ovary was polycystic. The uterus and left appendages were in all respects normal. The two right hydatids of Morgagni were larger than normal, and presented pedicles about 1.5 cm. long: the uppermost one resembled a ripe cherry in size and appearance. It was tense, and its pedicle was twisted on itself through 1½ turns in a counter-clockwise direction. The pedicle was ligated and the strangulated hydatid removed. The other hydatid was also removed, as the occurrence of a similar mishap seemed not unlikely in view of the abnormal length of its pedicle. A wedge-resection of the right ovary was done. The abdomen was closed without drainage. Convalescence was uneventful.

The points of interest in this case are: (1) the accurate simulation of acute appendicitis, and (2) the large amount of fluid poured out in six hours from a small strangulation.

MYOIDEMA

Myoidema is a physical sign which seems to have been almost forgotten, as it is not mentioned in some of the recent textbooks of medicine, and is not known to the younger generation of doctors. It is a localized contraction of wasting muscle, produced by a sharp tap, and is most often seen in cases of pulmonary tuberculosis. It is readily obtained by striking the pectoralis over the second and third ribs with the end of the middle finger, as if percussing rather forcibly. In all cases where the tuberculosis is active a small lump of muscle will at once arise at the stricken point and quickly disappear. It may be seen in other diseases where there is loss of flesh with febrile temperature. One condition is, so far as I know, peculiar to pulmonary tuberculosis, and that is, the presence of myoidema on one side of the chest only; this happens when there is active disease at one apex, and that slight. In the more advanced cases there is often a difference on the two sides as to the readiness of myoidema to appear, the more ready contraction being produced on the more diseased side. In acute cases it can be got in every muscle of the body. A very fair estimate of the rate of progress of the disease at the time is given by this phenomenon—the more readily it is produced the more acute the case, and, if it cannot be obtained, the tuberculosis is quiescent.

Consulting Physician to the Royal Sussex
County Hospital, Brighton.

Reviews

THE CLINICAL SIGNIFICANCE OF THE ELECTROCARDIOGRAM

Experimental researches and clinical studies during the past five years have enlarged and, to some extent, modified the clinical significance of the electrocardiogram. The new (third) edition of Dr. HAROLD PARDEE'S *Clinical Aspects of the Electrocardiogram*¹ presents a full and balanced picture of modern conceptions. Earlier chapters are devoted to the common abnormalities and a consideration of the limits of the normal. It is customary at the present time to regard an electrocardiogram as normal when it shows none of the irregularities of rhythm or complex which are known to denote functional or pathological changes in the heart. It cannot be doubted that the great mass of normal electrocardiograms contain groups of less obvious deformities, perhaps representing pathological changes, but more likely related to dysfunction of endocrine and metabolic mechanisms in or controlling the heart. These have yet to be differentiated, and may constitute some of the new matter that will appear in further editions of Dr. Pardee's monograph.

In the present volume the new knowledge of localization of myocardial damage, bundle-branch block, and premature contractions is discussed and the modern views justified. There have been those who have discounted the value of instrumental methods in clinical medicine; it has been assumed by some that electrocardiography is employed as a short cut to prognosis. No orthodox physician would make such a contention, and Dr. Pardee has epitomized the matter as follows: "The only thing that can be discussed about the prognostic importance of the electrocardiogram is the part which it may contribute to the prognosis"—namely, by indicating the extent of the structural changes in the myocardium. The volume contains seventy-four illustrations, the reproductions of electrocardiograms being adequate, but not outstandingly good. The text is full and readable, its authority is unquestionable, and the monograph will prove highly valuable to clinicians, and particularly to cardiologists.

INFANTILE ECZEMA

That baffling disease, eczema of infancy, is the subject of an interesting monograph,² by Dr. PÉHU and Dr. AULAGNIER, both of Lyons. Although for long the subject of intensive study, it cannot be said that much is yet known either as to its real nature or that the treatment of the condition is in any way satisfactory. The authors have recapitulated thoroughly enough the various views held on the vexed questions associated with the subject, including its aetiology, and finally side themselves with those who are content to explain so many things by the employment of the blessed word "allergy." The exact signification of this very popular term still remains obscure. According to some it is merely a synonym for general hypersensitiveness to environment, while others limit it to the liability to the production of toxic symptoms from the action of various proteins. In the case of infantile eczema most authors lay the blame on different articles of diet, especially upon milk, the staple food of infancy, but some indict the egg albumen consumed by the mother during the pre-natal life of the patient. At one time it was thought that eczema seldom

or never occurred in breast-fed infants, but it seems that the incidence of the complaint is almost the same in these as in those who are bottle babies. In any case it is never wise to wean prematurely a breast-fed baby with the idea of benefiting the eczema. Toxins produced in the alimentary canal have also often been cited as an aetiological factor, but well-nourished infants with no symptoms of digestive trouble are usually much better if their alimentary systems are allowed to remain undisturbed by unnecessary medicines.

Our authors in their discussion of the important but difficult subject of treatment relegate local measures to a secondary place, but they are sufficiently wise to warn against the employment of any irritating application, which is only too prone to cause an exacerbation of the condition. Their primary object in treatment is to remove the allergic susceptibility of the patient, and for this purpose they find that the best method is the employment of vaccino-therapy in the shape of injections of an enterococcal vaccine. They appear not to aim at a specific desensitization, but at an alteration of the reactive tendencies of the patient—an object very much akin to the purpose proposed by the advocates of "protein shock." Among other matters, the authors devote considerable space to the discussion of sudden death in infantile eczema—that is to say, death occurring within a few hours in an infant previously healthy except for the presence of the eczematous eruption, and in which post-mortem examination discloses no sufficient cause. These tragedies, fortunately rare, they regard as examples of anaphylactic shock, supporting their contention by a comparison of the microscopic changes found in the central nervous system in such cases with those found in animals which have been the subjects of experimental anaphylaxis. It is a singular thing that these cases, rare enough in France, seem practically unknown in this country; we cannot remember one being published for many years. In conclusion we may say that this monograph is worthy of perusal by all dermatologists and paediatrists.

SEXUAL AND REPRODUCTIVE PHYSIOLOGY

Among the branches of medical science in which new knowledge is so rapidly multiplying few, if any, have been so prolific in hypotheses and potentialities as endocrinology, and in particular the *Recent Advances in Sex and Reproductive Physiology*,³ on which Dr. J. M. ROBSON of the active Institute of Genetics of the University of Edinburgh has provided a comprehensive summary. This review is obviously valuable at a time when published researches are constantly appearing, sometimes discordant and even confusing from the introduction of new names for the same hormone. The endocrine interdependence is complicated, and even now it is difficult to decide whether all the described hormones have a separate existence or whether the different reactions reported are due to variations in the conditions present in the reacting tissues.

As is well known, Zondek described two gonadotropic hormones, prolan A and prolan B, manufactured in the anterior lobe of the pituitary, and probably by the basophil cells, which control the hormone activities of the ovary. Subsequently Wiesner of the Edinburgh Institute of Genetics set forth a similar scheme under the name of the Rho factors. That the anterior pituitary provides a gonadotropic hormone there appears to be general agreement, but considerable doubt has been expressed, for example, by Collip and Dodds, about the separate exist-

¹ *Clinical Aspects of the Electrocardiogram, including the Cardiac Arrhythmias*. By Harold E. B. Pardee, M.D. Third edition, revised. New York: Paul B. Hoeber, Inc. 1933. (Pp. 295; 74 figures. 5.50 dollars)

² *L'Eczéma du Nourrisson*. Par Dr. M. Péhu et Dr. R. Aulagnier. Paris: Gauthier-Villars. 1934. (Pp. 174. 25 fr.)

³ *Recent Advances in Sex and Reproductive Physiology*. By J. M. Robson, M.D., B.Sc. With an Introduction by Professor F. A. E. Crew, M.D., D.Sc. London: J. and A. Churchill. 1934. (Pp. ix + 249; 47 figures 12s. 6d.)

ence of two—prolan A and B. Dr. Robson, who gives a wide review of the whole subject, concludes, from the evidence of different types of urine and of various pituitary preparations, that there apparently are two gonadotropic hormones. Another disputed point is whether or not there is a definite increase of eosinophil or other kind of cells in the anterior pituitary in pregnancy; the author quotes an observation to the effect that there is a preponderance of acidophil cells; but it may be noted that Rasmussen, from a long series of histological examinations, does not recognize the existence of what have been called the pregnancy cells.

The question of a gonadotropic hormone secreted by the human placenta is discussed and left open. Although there are admittedly some reasons for the suggestion that the foetus produces a hormone influencing the course of pregnancy, the author concludes that there is not any convincing proof of this.

ULTRA-VIOLET THERAPY IN EYE DISEASE

For some years there has been a physico-therapeutic department at Moorfields Eye Hospital—recently under the charge of Mr. Frank Law, who has compiled a review of the action of this and other forms of radiant energy under the title of *Ultra-Violet Therapy in Eye Disease*.¹ Full details of the type of radiant energy employed are dealt with in an introductory chapter. Ultra-violet light is used in treatment of disease of the eye in two ways: in general phototherapy, as a means of increasing the patient's general resistance and recuperative power; and in local phototherapy, by virtue of its local biological action upon the tissues. The potency of such light in its effect on the eye was shown by Birch-Hirschfeld and Duke-Elder. There was a definite abiotic reaction following exposure to the short unfiltered ultra-violet rays. The cornea swelled in all its parts, there was a cellular infiltration, and, if severe, the lesion might extend to the production of opacity. The lens might be similarly damaged, even to a tendency to the formation of cataract. There is also some evidence that the retina may suffer injury, and it is obvious that unskilled use of these rays may be highly injurious to the sight. In Mr. Law's work some 225 cases come under review, mainly those treated in 1932, and special pains were taken to secure a proper follow-up. The largest number of cases comprised those commonly associated with the appearance of pterygiae either on the conjunctiva or on the cornea. In weighing the value of the results Mr. Law confesses himself less enthusiastic than previous workers. He points out that besides the use of the rays there are other factors in the treatment—the cleansing of the eye by a skilled nursing staff, and, not least, the mere exposure to the air of the bodies of children, and the removal of clothes that are often actually sewn on! Nevertheless, he is convinced that there is a benefit derived in cases of blepharitis, pterygular disease, and conjunctivitis in children; diseases that are due to bad condition, debility, lack of nourishment, or even lack of cleanliness. This finding is strengthened by the observation that poor results were achieved in such cases as syphilitic iridocyclitis and tuberculous disease. General phototherapy is an adjunct in treatment—in many cases a useful adjunct—so that the sooner it is begun the better the chance of performing its part in expediting recovery. There is a section on the use of radium. The types of rays and the means of control adopted at the Radium Institute are described. It is held that the claims made for the therapeutic value

of radium in ophthalmic conditions, especially in America, are too diverse and too enthusiastic, but that it is of proved value in the treatment of epibulbar and orbital neoplasms, as also in the treatment of spring catarrh. There are no indications that it will supersede present methods of treatment of trachoma and senile cataract. The book includes also a chapter on the therapeutic use of x rays, wherein, on balance, the dangers seem to outweigh the advantages; and a chapter on the use of infra-red rays, which serve no therapeutic purpose in ophthalmology, and, in fact, offer definite dangers.

ACUTE AURAL INFECTIONS

In *Acute Otitis and Mastoiditis in General Practice* Mr. N. ASHERSON has made a determined attempt to produce a book which may help the practitioner, faced as he often is by the puzzling phenomena occurring in acute inflammatory conditions of the ear. Had the author been able to convey to his readers in clear, concise language the fruits of his experience, which is evidently wide, he might truly have been very helpful. Quite early in the book, however, in giving directions to the practitioner for so simple a matter as syringing, he says, "The nozzle of the syringe is inserted into and along the floor of the meatus," the italics being the author's. If this be the method which a practitioner should adopt perhaps it explains why many patients still prefer to visit an aural surgeon when the ears require syringing. Again, we read: "The tip of the mastoid process is subcutaneous, and its anterior, lateral, and posterior parts are palpable, but the actual tip itself is buried in the uppermost fibres of the sternomastoid muscle." Such loose writing makes every sentence suspect, and there is hardly a page on which some obscurity or ambiguity is not to be found. On page 160 it is stated that after an operation for acute mastoid the average period before the patient is fit for normal routine is six weeks, and on page 276 the average period is given as three months. When he reads that the mastoid antrum holds only a drachm of pus at the most the reader will wonder what the author really means. Spelling mistakes are not infrequent, but perhaps "Wylde's" incision conceals a delicate gesture which the father of Oscar would not have appreciated. If the author had submitted his book to independent and drastic revision good use could have been made of his excellent material.

BLOOD LYMPH AND IMMUNITY

Investigations of normal and pathological body processes are apt to be made in different institutions and published in different journals. It is therefore a great help to workers in both fields if a summary of the present state of knowledge in both directions is collected in one volume. This is attempted in the *Treatise on Physiology, Normal and Pathological*,² edited by Professors ROGER and BINET. The second edition of the volume of this treatise, which deals with blood lymph and immunity reactions, has recently appeared. The 730 pages cover a very wide range, including, for example, the chemical constituents of the blood, blood transfusion, and immunity reactions.

The book is divided into sections on various subjects by different authors. These sections are of very unequal quality. That dealing with the chemical constituents of the blood (Professor Laudet) is concise and nearly as

¹ *Ultra-Violet Therapy in Eye Disease. With a Review of the Action of Other Forms of Radiant Energy.* By Frank W. Law, M.A., M.D., B.Chir., F.R.C.S. Foreword by Sir Stewart Duke-Elder, M.A., D.Sc., M.D., Ph.D., F.R.C.S. London: John Murray. 1934. (Pp. 78. 5s. net.)

² *Acute Otitis and Mastoiditis in General Practice. A Manual for Practitioners and Students.* By N. Asherson, M.A., M.B., B.S., F.R.C.S. London: H. K. Lewis and Co. Ltd. 1934. (Pp. 317; 97 figures, 12 in colour. 10s. 6d. net.)

³ *Traité de Physiologie, normale et pathologique.* Tome vii, Sang et Lymphes Reactions d'Immunité. Publiée sous la direction de Professeur G. H. Roger et Professeur Léon Binet. Deuxième édition. By various authors. Paris: Masson et Cie. 1934. (Pp. 730; illustrated. Broché 100 fr., relié 120 fr.)

complete as is possible in sixty-eight pages, although practically nothing is said about the reaction of the blood. There is a thorough discussion of the coagulation of the blood by Professor Zunz. On the other hand, Professor Achard gives a vague and verbose discussion of theories of oedema, in which he does not appear to distinguish between osmotic pressure and hydration of proteins. Had he cleared his ideas and included more of the known facts (as, for example, those of Moore and van Slyke bearing on the relation of oedema to plasma proteins) he could have presented far more information in fewer pages. The single page given to the pathological physiology of blood platelets is most inadequate. Anaemias and leukaemias are not included. The section on respiratory pigments in invertebrates is very brief, while that on coagulation of the blood in invertebrates occupies less than a full page. The section on immunity, by Professor Bordet, is masterly, as far as it goes, but makes little mention of the great volume of work carried out in the last ten or so years. It entirely omits the work done by Landsteiner's school on the relation of specificity to chemical structure. In the section on anaphylaxis, by Professor Besredka, considerable attention is paid to the practical aspects of the subject. This is all to the good, for it maintains interest and counteracts a too academic outlook. But it appears inadvisable in a work of this nature to include a purely practical section on blood transfusion, particularly at the expense of other important matter.

In such a treatise full references are essential in order that the reader may be able to form his own opinion on the work which the author quotes and to look up details that the author has omitted. No references are given in some sections; in others the bibliography is most incomplete. In all the sections little work is quoted except that published in French journals. There is no index.

Notes on Books

An Introduction to Pharmacology and Therapeutics,¹ by Professor J. A. GUNN, was first published in 1929, but has already reached a fourth edition. The continued demand for this book is proof that there is a widely felt need for some short and simple exposition of the scientific facts which form the basis of rational therapy. The author modestly attributes the success of his book to a revival of interest in the treatment of disease, but its popularity is chiefly due to the fact that, while it is concise, it is also readable and accurate.

¹ *An Introduction to Pharmacology and Therapeutics*. By J. A. Gunn, M.A., M.D. Fourth edition. London: H. Milford, Oxford University Press, 1934. (Pp. 237. 5s. net.)

Murrell's handbook *What to Do in Cases of Poisoning*² has now reached its fourteenth edition, and for the last three Dr. PHILIP HAMILL has been responsible. The edition under review has been carefully revised, and many new poisons have been added. We find, for example, accounts of dinitrophenol intoxication, the use of strychnine in barbiturate poisoning, and antimony poisoning from enamel-ware glaze. The long-continued popularity of this pocket volume is the best proof of its merits. We suggest, however, that its utility might be increased by a somewhat fuller account of the commonest causes of poisoning, such as coal gas and lysol.

The first volume of the forty-fourth series of *International Clinics*³ is divided into four parts, devoted respectively to original articles on medicine, surgery, and paediatrics, and reviews of recent progress in medicine and surgery. The section on medicine contains instructive papers by Noel Fiesinger of Paris on hepatic insufficiency, by Lay Martin of Baltimore on jaundice, by Tinsley R. Harrison of Baltimore on enlargement of the heart, by William S. Lowe of Baltimore on so-called functional heart disease, by G. L. W. Gorham and K. E. Crouse of Albany on recent advances in the treatment of cardiac and renal oedema, by Henry M. Moses on the management of old-age conditions, and by Samuel Weiss and Vera L. Coles on the role of the vegetative nervous system in gastro-intestinal diseases. The section on surgery contains an interesting paper by I. A. Bigges and William B. Porter of Richmond, Va., with a record of seven personal cases and a review of the literature. The sections on paediatrics consist of a symposium on lead poisoning in its various aspects, including its occurrence in children, by H. B. Cushing and H. S. Mitchell, x-ray diagnosis by H. E. Childe, its biochemical aspects by I. M. Rabinowitch, the pathology by Lawrence J. Rhea, and treatment by S. G. Ross, all of Montreal. Recent progress in medicine is discussed by A. Cantarow of Philadelphia, and in abdominal surgery by Donald C. Balfour and James R. Watson of Rochester, Minnesota.

The British Social Hygiene Council (Carteret House, London, S.W.1) has published a thirty-four-page booklet entitled *Health Notes for Young Men Overseas*, which provides suitable information on venereal diseases, etc., intended for young employees of tea, rubber, and other firms going to the East. It has been prepared by Dr. T. DRUMMOND SHIELDS on the lines of the Ross Institute booklet on malaria, and can be obtained for 4d. Up to 25 per cent. of free copies are offered to firms placing an order for these booklets.

² *What to Do in Cases of Poisoning*. Edited by P. Hamill, M.D., D.Sc., F.R.C.P. Fourteenth edition. London: H. K. Lewis and Co. Ltd. 1934. (Pp. viii + 204. 5s. net.)

³ *International Clinics*. Vol. i, forty-fourth series, 1934. Edited by Louis Hamman, M.D. Philadelphia, Montreal, and London: J. B. Lippincott Company. 1934. (Four volumes quarterly. 50s.)

Preparations and Appliances

IRRIGATING REPOSITOR FOR CATARACT EXTRACTION

Mr. B. W. RYCROFT, F.R.C.S. (London, W.), writes: During the operation of cataract extraction it is frequently necessary to irrigate the anterior chamber in order to remove residual lens cortex after the nucleus has been extracted. Thereafter

point, and slightly curved on the flat. This is mounted on a handle, to which is fitted a small nozzle for attachment of a rubber tube, around which the whole shaft is balanced. The diameter of the tube is little more than that of an ordinary iris repositor, and can be inserted between the lips of the corneal section without causing the wound to gape. Further-

the iris is replaced and the edges of the wound cleared of capsule, etc. In order to complete this double manoeuvre by a single instrument an irrigating repositor has been constructed, and has proved satisfactory in practice.

The instrument (shown in the accompanying figure) consists of a fine bone hollow tube of silver tapered to a narrow

more, it may be easily passed to the lower limits of the anterior chamber in order to obtain a reverse flow and to dislodge stubborn masses of lens cortex. The rate of flow is controlled by either hand.

The instrument is constructed by John Weiss and Co., Oxford Street, London, W.

MANCHESTER MEDICAL SOCIETY CENTENARY

BY

E. M. BROCKBANK, M.D.

Manchester has been, is, and will be celebrating centenary anniversaries of important societies in the conception of all of which the medical profession had been more or less active. Last year the Statistical Society, the first of its kind in England, reached its hundred years of existence. One of its first four founders was Dr. James Phillips Kay, afterwards Sir James Kay-Shuttleworth (1804-77), a baronetcy being awarded for his national services to education. Presidents of the society were Dr. John Robertson (1844-7), Dr. Daniel Noble (1859-61), and Dr. James Niven (1905-7). I had the honour of giving the society an account of "A Medical Statistician of a Century and a Half Ago" (Dr. Thomas Percival) during its historical celebrations. This year the Manchester Medical Society became a centenarian on October 1st; and next year the Manchester Athenaeum—practically a similar institution, but for the commercial man in the street—reaches a similar age. In a *History of the Manchester Medical Society* it is suggested that the idea of both our own society and of the Athenaeum was conceived, and preliminary steps for their formation taken, by one man—John Walker—a surgeon of the town. As much as is known of Walker is recorded in the *History* of the society which has been prepared for the centenary. Before 1834 there was no medical library available for general reference, and no society confined to members of the profession at which medical questions could be ventilated.

FROM 1782 TO 1834

The Manchester Literary and Philosophical Society was conceived and really brought into being in 1782 by Dr. Thomas Percival of medical ethics fame, with the forceful assistance of Thomas Henry, F.R.S., apothecary to the Manchester Infirmary—that is, a general practitioner of the day—and the Rev. Thomas Barnes, Unitarian minister of the town. This society was mainly run by the profession for thirty or more years, half of the offices—presidents, treasurers, secretaries—being filled by our forebears. In its early days the doctors read papers before it, but they were mainly of general interest, and any member of the society could attend its meetings. The only method in which professional matters could then be discussed seemed to be by the public press, in pamphlets, and even in octavo volumes of considerable size. Our forefathers of the day were no milk-and-water controversialists; ink was no use to them—gall apparently flowed more naturally from their quill pens. The most important controversy of those times was over the justifiability of the Caesarean section operation, which Dr. John Hull defended against the scathing comments of William Simmons, backed up by Dr. John Ferriar. Then Charles White drew down the sneers of Ferriar upon his method of describing the anatomical distribution of the swelling in phlegmasia alba dolens puerperarum. All in public too, and no doubt spicy material for the general readers.

A HUNDRED YEARS OF ACHIEVEMENT

In spite of the evident need for one, there was no attempt to found a purely medical society until 1833, when a meeting was held and a decision made to canvass the practitioners of the district on the question. Two energetic young persons—John Walker and Joseph Peel Catlow—undertook this, and the result was the foundation next year of a society with the object of providing a library and reading room and place for meetings for discussing medical topics. Dr. John Hull, then the doyen of the profession, was elected first president.

The history of the society, with its ups and downs, hard work by some members, indifference by others, financial struggles, is probably that of other societies: but one outstanding feature was the acquisition of a very extensive and valuable library through the efforts of

Thomas Windsor, an ophthalmic surgeon of distinction in his day. For fifteen years he bought many thousands of second-hand books from home and abroad. Among them were some dozen incunabula, many examples of fine printing from the leading Continental presses, anatomical plates, biographical dictionaries, sets of periodicals—indeed, anything that might be of value for reference or research. So much was spent on these books that the committee got restive, and the end was Windsor's withdrawal from his library activities and transference of his help to Dr. Billings's library of the United States Surgeon-General at Washington.

The actual hundred years of achievement was reached on October 1st, on which date an exhibition of books, portraits, curios, and other objects bearing on the medical history of the town was opened in the new Central Library of the city, where it will remain for general inspection until October 20th. The president of the society for the year, Dr. E. Bosdin Leech, gave an address on October 3rd, the first Wednesday in the month, on which ordinary meetings of the society have invariably been held from October 1st, 1834. His subject was "Some Picturesque Episodes of Manchester Medical History." Before the address Dr. Leech presented, for the honorary membership of the society, the Earl of Crawford and Balcarres, Chancellor of the University, Sir Walter Moberly, Vice-Chancellor, Mr. Walter Cobbett, Chairman of the Board of Trustees of the Manchester Royal Infirmary, Percy Winstanley Hull, grandson of Dr. John Hull, the society's first president, Dr. J. M. Bligh, President of the Liverpool Medical Institution, and Professor J. A. Nixon of Bristol, who is to address the society next month on "Licence to Practise and Liberty to Teach Medicine in the English Provinces." A dinner followed on the same evening, at which many distinguished visitors were present. On Sunday, October 7th, there was a special service in the Cathedral, the preacher being the Right Reverend Cecil Wilson, Bishop of Middleton.

THE COMMEMORATIVE EXHIBITION

The exhibition is in the large hall of the new Central Library of the city, recently opened by the King, which has been designed for such a purpose. The display, mostly of objects illustrating the medical history of the town, is well worthy of the honour of being the first of its kind to appear in such a striking place. It is being visited daily, with great interest, by hundreds of the general public, for whom it was chiefly intended. The exhibits are disposed in handsome erect metal and glass cases, while for the larger articles and books horizontal cases are used. Of books there are samples of medical publications of the fifteenth and sixteenth centuries, from the most famous Continental presses, some in Greek characters. More modern books illustrate the writings of local doctors who have promoted the knowledge of medicine. Most of these exhibits are made more interesting by a portrait of the author displayed by the side of his book. Two cases contain books and pamphlets dealing with the vaccination controversy before 1816, and copies from burial registers of the town churches showing the ravages of small-pox, especially among children, of the period. One very interesting exhibit is a series of illustrations and portraits showing the growth of the Manchester Royal Infirmary from its foundation in 1752, and a group of its original large gallipots and poison bottles, the latter like large stone ginger-beer bottles of last century. Among other objects which attract attention is a carbolic acid spray, given by Lister to the late Mr. Edward Lund. The progress of the public health of the town is well illustrated by graphs, especially made for the purpose, with singular clarity of exposition.

A final note of personal interest is that the president for the centenary year is nephew of the late Dr. Daniel John Leech, professor of materia medica and therapeutics in the University of Manchester, who filled the same office in the jubilee of the society fifty years ago. Dr. D. J. Leech was keenly interested in the nitrite group, and was instrumental in having that very useful preparation liquor ethyl nitritus recognized in the official *Pharmacopoeia*, though it is no longer there.

LEWISHAM HOSPITAL EXTENSION

OPENING BY LORD DAWSON

A new ward block at Lewisham Hospital—one of the general hospitals of the London County Council—was opened on October 9th by Lord Dawson of Penn. The block consists of three wings, and comprises a maternity department with accommodation for sixty-three cases, a children's section with thirty-five cots, and two general wards containing sixty-six beds. The total additional accommodation provided in the extension is 164 beds. In the maternity unit the main wards are divided into three, and at the end is the babies' "crib ward," with toilet room. There are five labour rooms, a bathroom for newborn babies, and a room, specially heated and thermostatically controlled, for babies born prematurely. The children's section includes an admission bathroom, a milk room for the preparation of feeds and the sterilization of bottles, and a sun parlour. Glazed divisions between the sections give a less institutional appearance, and aid in the classification of patients. In addition to the ordinary examination lamps, there are plugs for use in connexion with x-ray examination by each bedside, and wireless earphone points for each patient. The new works, including equipment, are expected to cost £55,500, and will bring the total accommodation of the hospital, which had 5,635 in-patients last year, to 747.

The opening ceremony was largely attended by members and officers of the London County Council and by a number of consultants and specialists in its service. Mrs. Nellie Palmer, chairman of the Lewisham Hospital Committee, presided. Mr. Somerville Hastings, chairman of the Hospital and Medical Services Committee of the Council, in welcoming Lord Dawson, said that this new block was the biggest piece of constructive work that the Council had undertaken since it became responsible for municipal hospitals in 1930. It was believed, and hoped, that the wards were thoroughly up to date, and efficient in every way, and it was known how very necessary they were in a rapidly growing district. The available beds in connexion with L.C.C. hospitals were constantly being increased, and a few weeks' time another hospital would be taken over—namely, Heatherwood Hospital, with more than 100 beds, presented by the United Services Fund. Mr. Somerville Hastings pleaded for the development of after-care work, which must be of a voluntary nature, in connexion with the hospitals. He wanted to see efficient Samaritan committees formed at each institution.

Lord Dawson of Penn, who wore his gown as president of the Royal College of Physicians of London, said that he was present not only in his personal capacity, but as President of the College. The two Royal Colleges comprised in their Fellowship a large proportion of the members of staffs of the leading hospitals of the country, and had accumulated in the course of years a certain amount of knowledge and experience which they were only too anxious to place at the service of any forward movement which would improve hospital services in this country. He paid a tribute to Sir Frederick Menzies, the county medical officer of health, on whom, as the greatest medical administrator of our time, his College had conferred its honorary Fellowship. In addition to the vast amount of work imposed by the Local Government Act, 1928 there had fallen to Sir Frederick Menzies a very large share in the establishment of the Post-Graduate Hospital and School at Hammersmith, now

approaching completion. Lord Dawson sketched the wide compass of the medical services of the L.C.C., and referred to the increasing co-operation with the voluntary hospitals. The L.C.C., with great wisdom, had associated its new hospitals with the right conception of teaching. One practical issue was the linkage of municipal hospitals for teaching purposes to the teaching hospitals of London. Passing to the building which he was to open, Lord Dawson said that it was a great pleasure to be in a building in which such fastidious care had been spent on details of construction—on the proper provision of light and air, and on the width and height of wards. He congratulated the hospital on the fact that it stood in more than ten acres of grounds. It was elementary foresight on the part of any hospital or clinic, private or public, to acquire more ground than it could immediately use, for no one could say in what large direction hospital construction might make progress during the next fifty years. He praised, also, the provision for maternity cases, which would help to make child-bearing safe. He hoped that in course of time all the municipal health services of the district would be located within the hospital, instead of being scattered at various centres. Finally, he stressed the need for a department of physiotherapy in connexion with all hospitals.

By means of a microphone Lord Dawson addressed a few words of encouragement to the patients, who were listening-in, and then he and the general company proceeded to inspect the block.

ROYAL MEDICAL BENEVOLENT FUND

Subscriptions and donations are very urgently needed in order that the activities of the Fund may be maintained. Legacies are needed to support the annuity department. Cheques should be made payable to the Honorary Treasurer, Royal Medical Benevolent Fund, 11, Chandos Street, Cavendish Square, London, W.1.

The committee at a recent meeting voted seventy-two grants amounting to £1,513 10s. The following are particulars of three out of the many cases helped.

M.S., F.R.C.S., aged 58, married, with three children, aged 16, 14, and 12. Joined up for the war, and was in France from 1915 to 1917, when he retired on account of ill-health. Then followed a long period of locums, with a growing family to educate. Two years ago he started in a practice of his own. In July, 1934, the applicant was admitted to hospital, and had an operation for pyloric stenosis. It was found that he had suffered from a duodenal ulcer for some years. It was clear that this man had been struggling to build up a practice to support his family while seriously ill. He will require a long holiday after his discharge from hospital. He has no savings to meet this, nor for the support and maintenance of his family, and there are some pressing debts. The Fund has given immediate assistance of £30, and help has been obtained from other societies amounting to £157. Total charitable gifts, £187.

Widow of L.R.C.P. and L.M. The husband died suddenly in 1923 from heart disease. The widow, aged 30, was left inadequately provided for with three young children. She has sought employment, and has worked as nurse and housekeeper, but was recently dismissed owing to breakdown in health. The eldest daughter has now reached the age for employment, and is earning £83 per annum; the two younger are at school. The Fund and Ladies' Guild are assisting with grants amounting to £56. The total income available for food and household needs for this family is £167, which has also to meet children's extras at school, fares, and outfit, but excluding school fees.

Widow of L.R.C.P. and S. The husband died in 1931, leaving his widow, aged 46, with a family of five children. Fortunately three were able to earn and contribute £147 to their mother towards their own maintenance. The Fund gives a yearly grant of £25 and the Ladies' Guild £19 10s. Total income is £197 10s.; rent and rates, £58, leaving £139 for the maintenance and household needs of six persons.

CENTENARY OF THE UNIVERSITY OF DURHAM COLLEGE OF MEDICINE

CELEBRATIONS IN NEWCASTLE AND DURHAM

On October 4th and 5th the Newcastle School of Medicine celebrated the hundredth anniversary of its foundation. Coeval with the federal University of which it is one of the most flourishing units, it began its work in 1834 in a humble fashion. The present building, dating back to 1888, is the third home of the school, and plans are already far advanced for the erection of a new College in close proximity to the Royal Victoria Infirmary, since for some years the number of applicants for admission has considerably exceeded the capacity of the laboratory accommodation in several departments, and even continued duplication of classes has failed to meet the needs

from other schools unable to send personal representatives, including a congratulatory cable from the Dean of the Faculty of New York. Dr. E. K. Le Fleming, Chairman of Council, personally represented the British Medical Association. The Chancellor of the University of Durham, Lord Londonderry, detained in London by urgent affairs, sent a message of congratulation and good wishes. The Visitor of the University, the Lord Bishop of Durham, and the chief officers of the sister colleges at Durham and Newcastle were present, together with the Lord Mayor of the city and a distinguished assemblage from the city and the counties of Northumberland and Durham.

UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-UPON-TYNE: NORTH FRONT.

of students and permit all eligible candidates to enter the school. On Thursday, October 4th, the College was thrown open to visitors. The chief features of interest were historical exhibits by Professor Grey Turner, Dr. W. D. Arnison, and Mr. F. C. Pybus; and demonstrations in the departments of anatomy, biology, physiology, chemistry, and pathology.

OFFICIAL RECEPTION

The president, Sir Thomas Oliver, who has been associated with the College for fifty-five years since his appointment on the teaching staff in 1879, welcomed guests at the official reception in the evening. Congratulations were offered in person by the Presidents of the Royal College of Surgeons of England, the Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow, the Governor of the Apothecaries' Hall of Dublin, the President of the British College of Obstetricians and Gynaecologists, the Deans of the Faculties of Medicine of Aberdeen, Oxford, Leeds, and Sheffield, the Provost of the School of Medicine of the University of Wales; whilst messages were received

Among the many messages from old graduates unable to attend were notably those of Dr. Milner Moore (at the age of 95 years) and Dr. Alfred Cox. The scene in the Great Hall of the College was enlivened by the vivid colour of the academic costumes of graduates and the representative guests. Alternative attractions were provided in the way of a lantern lecture on the history of the College by Professor Grey Turner, an anatomical film demonstration by Professor Green and Dr. James Whillis, and a picturesque display of the local traditional sword-dancing by a team, whose age averaged 60 years, led by a veteran of 77 years. Later, guests and graduates and students danced till the early hours.

On Friday, October 5th, at Newcastle-upon-Tyne, old graduates, under the guidance of Dr. W. D. Arnison, visited the Old Infirmary, now manufacturers' premises, identifying where possible the scenes of their hospital life. Others visited the various hospitals associated with the school, the Bacteriological Department, and the Public Health Laboratories. Sir Francis Acland, Chairman of the Dental Board of the United Kingdom, and Sir Holburt Waring were among the visitors to the Sutherland Dental School of the College.

CONVOCATION FOR HONORARY DEGREES

Guests were then transported by private cars and omnibuses to Durham, where in the Great Hall of the Castle luncheon was served to over two hundred guests, including the Chancellor, who had flown from London, the Visitor, the Vice-Chancellor, the Minister of Health, Sir Francis Acland, Sir Holburt Waring, Dame Janet Campbell, and Lieut.-General Hartigan, Director-General of the Army Medical Services.

A special convocation followed in the Chapter House of Durham Cathedral, with the Chancellor presiding, when honorary degrees were conferred. Sir Hilton Young, the Minister of Health, was presented by Sir Robert Bolam, and Sir Holburt Waring, P.R.C.S., by Professor Grey Turner, for the degree of D.C.L. Sir Francis Dyke Acland, Chairman of the Dental Board, was presented by Sir Thomas Oliver, and Dame Janet Campbell, M.D., by Professor Ranken Lyle, for the Degree of Doctor of Hygiene. Lieut.-General J. A. Hartigan, D.G.A.M.S., and Dr. Joseph W. Leech, M.P., were presented by Professor Grey Turner for the degree of Doctor of Surgery, and Dr. William Robinson of Sunderland for the same degree by Professor Thomas Beattie. Lastly, Dr. W. D. Arnison, joint author with Professor Grey Turner of a commemorative volume, *The Newcastle-upon-Tyne School of Medicine, 1834-1934*, was presented for the honorary M.A. by Professor C. E. Whiting. This handsome book, with abundant pictures,¹ forms an interesting memento

THE LEAGUE AND TRAFFIC IN OPIUM

[FROM OUR GENEVA CORRESPONDENT]

The Council of the League of Nations, on September 24th, received the voluminous report of the permanent Central Opium Board—a document containing over a hundred foolscap pages of statistics. The drug traffic may not be controlled, but it is certainly fully analysed. The representative of Poland, M. Beck, in presenting the report to the Council, drew attention to what he considered the most important conclusion, that while in 1932 there was a general decrease in the manufacture of the three main drugs—morphine, diacetylmorphine, and cocaine—in 1933 there was a considerable increase in the manufacture of the first (11.52 per cent.), and a slight increase in the manufacture of the second and third. There had been, however, a marked decrease in the reported world consumption of diacetylmorphine (10 per cent.), and a less marked decrease in that of cocaine (4 per cent.).

INTERNATIONAL CONTROL OF NARCOTICS

M. Beck said that it was gratifying to learn that certain Governments whose countries are producers and exporters of large quantities of raw opium, such as Turkey and Persia, are showing an ever-increasing spirit of collaboration, and endeavouring to conform more and more with the methods of the Board; but he regretted that the international control over the raw materials for the manufacture of cocaine was seriously hampered by the fact that certain countries, including some of the main producers of coca leaves, do not send in statistics. He added that the Board was justifiably concerned at the considerable increase in its duties and responsibilities resulting from the application of the convention of 1931 for the limitation of the manufacture and regulation of the distribution of narcotic drugs.

From the battalions of statistics presented in the report it appears that the manufacture of morphine and of cocaine is diminishing in Germany and France, and that of morphine is increasing somewhat in Belgium and Italy. In the United Kingdom the manufacture of morphine in 1933 was to the extent of 1,873 kilograms, comparing with

for those who joined in the centenary proceedings; it is also a mine of information about the rise of a great medical school, with many biographical sidelights upon the leaders of the profession in Newcastle during the past hundred years.

THE BISHOP'S ADDRESS

The closing ceremony was a magnificent commemorative service in Durham Cathedral, at which the Visitor of the University, Dr. Hensley Henson, Bishop of Durham, gave an apt and inspiring address, thus rounding off the part he had played in a memorable occasion. "Perhaps we may distinguish," he said, "three main reasons why the College of Medicine, as it reviews the first complete century of its existence, may in its corporate capacity offer thanks to Almighty God. In the first place, there stands the continuance throughout the whole period of that settled civil order and complete liberty of thought and teaching which are indispensable conditions of scientific research and academic teaching. In the second place, you have to thank God for a succession of great teachers who have advanced medical and surgical science to its present amazing altitude. In the third place, you thank God for the continuing prosperity of the College. It has grown from small beginnings to a position of assured importance in the national system. Its students are found in every part of the Empire, exercising their noble and beneficent profession. In Newcastle itself the College has had to its hand a teaching instrument of the highest value in a famous hospital, which certainly takes a place among the greater hospitals of England."

1,292 in 1932. The manufacture of cocaine in this country is also rising slightly, reaching 427 kg. in 1933; having increased every year since 1929, when it stood at 238 kg. The largest manufacturer of morphine last year was the United States (7,459 kg.), and the largest manufacturer of cocaine was Japan (920 kg.). The greater part of the morphine produced in all countries is used in the manufacture of substances not covered by the convention. Thus, in the United Kingdom, out of the 1,873 kg. manufactured last year 111 was used in the manufacture of diacetylmorphine, 848 in the manufacture of non-convention substances, and 914 kg. remained as morphine. Some very curious facts are elicited by a glance at these tables. For example, Latvia and Esthonia are the largest consumers of galenical preparations of Indian hemp, each using 17 kg. per million inhabitants, whereas the United Kingdom consumes 9 kg. per million and France only 2 kg. The largest consumer of cocaine is Japan (14 kg. per million inhabitants), and in Europe, apart from an enormous consumption in Iceland, which may be disregarded, the largest consumer is France (nearly 9 kg.), followed closely by Belgium, Austria, and Latvia. The consumption in the United Kingdom is just upon 5 kg. per million.

MORPHINE FROM POPPY STRAW

In the discussion on dangerous drugs which took place in the Fifth Committee of the Assembly reference was made to the new Hungarian method of morphine extraction from poppy straw.¹ The Hungarian Government has the right to use this process, which enables it to assist the Hungarian peasants, and results in a reduction in the price of morphine. The representative of Poland said that his country also was interested in this new method, and would take it into consideration for the manufacture of codeine. If the process proved satisfactory from the economic standpoint it would be adopted, for it also carried advantages from the agricultural point of view. If several countries adopted the process smuggling would be reduced to zero, as every country would become quasi-independent of opium imports; on the other hand, correspondingly greater attention would have to be paid to internal supervision.

British Medical Journal

SATURDAY, OCTOBER 13th, 1934

ADVANCES IN TREATMENT OF TROPICAL DISEASE

A review of the work of the Calcutta School of Tropical Medicine since 1920 has been written by the Director, Lieut.-Colonel R. Knowles, I.M.S., and this appears as a supplement to the annual report for 1933. The review shows a record of useful and important activities in all branches of tropical medicine, but it is of particular interest in that it demonstrates what remarkable therapeutic advances have been made in recent years in tropical diseases, and what an important part the Calcutta school has played in these advances. The treatment of kala-azar is perhaps the most sensational of the successes. This disease invaded India some centuries ago, and spread over Bengal and Assam during the latter years of the nineteenth century. No cure was known, and the mortality was not less than 70 per cent. In 1915 treatment by antimony tartrate was discovered in Italy, and Sir Leonard Rogers introduced it into India. This treatment was brilliantly successful, but was prolonged, since thirty injections spread over three months were required, and a mortality of 10 to 20 per cent. still occurred. Since 1920 intensive investigations have been carried out with organic pentavalent antimonials, and now it is possible to cure kala-azar with eight injections, and the mortality is less than 5 per cent. As a result of these advances mass treatment properly carried out leads to the eradication of the disease in an infected area.

In the case of malarial therapy the advances, although not sensational, have been extremely important. In 1920 quinine was regarded as the sole remedy. Since then the Calcutta school has demonstrated that the total alkaloids of cinchona bark constitute an equally efficient and cheaper remedy, and has helped to establish the value of plasmoquine for destroying sexual forms of the parasite and thus rendering the patient non-infective to mosquitos. Atebrin, a synthetic compound which is a possible rival to quinine in the treatment of malaria, was tested fully in the school before being released for sale, and the most recent reports show that the drug is superior to quinine in cases of malignant tertian, and is indicated in special conditions, such as quinine idiosyncrasy, blackwater fever, and pregnancy. The school has also performed a most important service in discovering a form of monkey malaria. This should prove of great value in the experimental study of malarial therapy.

Hookworm infection is another disease of considerable economic importance in the therapy of which great progress has been made in the period under review. In 1922 the use of carbon tetrachloride was introduced into India, but the drug was found to be undesirably

toxic to Indian populations, and from 1924 onwards investigations have been pursued on the use of carbon tetrachloride combined with oil of chenopodium. Experimental work during the last year has shown that carbon tetrachlorethylene is less toxic than carbon tetrachloride, and a combination of carbon tetrachlorethylene with oil of chenopodium is recommended as the best treatment for hookworm infection. These researches on intestinal helminths have led to advances in the treatment of a variety of infections. It has been shown that Indian santonin is just as effective as the very expensive Russian santonin in ascaris infections, and hexyl-resorcinol and carbon tetrachloride have both been found to be efficacious against tapeworm.

In the case of amoebic dysentery the outstanding advance in treatment was the introduction of emetine injections by Sir Leonard Rogers in 1912. This drug has been very successful in acute cases, but in chronic cases and in carriers it is much less satisfactory. The alkaloids of kurchi bark, when first investigated, gave excellent results, but later results were disappointing owing to errors in the preparation of the remedy. Last year, however, the drug carbarsone was found to be of great value in this condition. This organic arsenical was originally produced by Ehrlich in 1909, and Leake demonstrated its amoebicidal action a few years ago. The results obtained in Calcutta have been very satisfactory, and Colonel Knowles believes that its introduction may prove one of the most notable of recent advances in tropical medicine.

The therapeutic advances we have mentioned represent only a small proportion of the valuable work carried out by the Calcutta School of Tropical Medicine, but they show clearly enough the remarkable rate of progress in the treatment of tropical diseases. The outstanding feature of the last fifteen years has been the introduction of synthetic chemotherapeutic agents. For example, this report contains an account of the successful use of the following: neostibosan, plasmoquine, atebrin, carbarsone, and hexyl-resorcinol. We have to acknowledge with regret that not one of these compounds was discovered in this country. The Calcutta school is doing splendid experimental therapeutic work, and it is a pity that it should be forced to obtain so many of its weapons from outside the British Empire.

INHIBITORY HORMONES

The number of active hormones which are nowadays considered to be present in the circulating blood must often seem not a little bewildering. The blood is by far the most complex fluid we know, and the co-existence in it of hormones, enzymes, antibodies, proteins, carbohydrates, lipoids, salts, cells, and metabolic products presents a picture which is well-nigh impossible to grasp in its entirety. Each of these substances, whether it exists in chemically large quantities or only in pharmacologically or histologically recognizable amounts, reaches its appointed place and exercises its specific function apparently unaffected by

the presence of the others. By what remarkable circumstances this is made possible it is hard to conjecture. Are the physico-chemical conditions of the blood such that no important interaction can occur between the hormones and other physiologically active principles, or are the structures of all these bodies such that they cannot interact chemically? The latter seems the less likely view, but as we are yet ignorant of the chemical structure of the greater number of hormones we cannot be certain. Of course, important chemical reactions do occur in the blood, as, for example, the mechanism of transference of oxygen and carbon dioxide, and the buffering of the blood; but even in these cases there is no important change in the basal structure of the interacting bodies; indeed, the value of these reactions lies in their ability to maintain the *status quo*.

This tendency to keep the state of the blood within relatively very narrow limits of variation is one of the most remarkable of biological phenomena. Not only is this the case for the familiar chemical constants, but it is even more striking as regards the bacterial antibodies. With the latter we are dealing with a type of reaction of the organism which is not usually considered from the physiological point of view as an instance of what is called "homeiostasis." We think, however, that it should be so regarded, and some recent work of Collip¹ would appear to make it necessary to extend the conception of homeiostasis even further. Collip points out that evidence is accumulating which shows that substances are produced in the body exercising an inhibitory action on certain hormones. Of the antagonistic action of certain hormones some knowledge has already been gained. The familiar antagonisms of insulin and adrenaline, of insulin and the diabetogenic component of the anterior pituitary, are well known. Less generally recognized is the resistance of certain animals (the rabbit, for example) to parathormone, but every clinician is familiar with the high tolerance of certain subjects to thyroid. The increased resistance of subjects with a high temperature to insulin is also appreciated, though not explained. These examples engender a suspicion that the body in certain circumstances can oppose the action of a hormone. Collip has shown that long-continued administration of the thyreotropic hormone of the anterior pituitary led to a condition of resistance and non-reactivity, and—a most important point—that the serum of the resistant animal when injected into a normal animal produced a similar condition of resistance in the latter. It was further shown that the serum of a horse treated for some months with the growth factor of the pituitary can inhibit the effect of the latter on the hypophysectomized rat.

Other instances of the presence of inhibitory hormones have been described, and Professor Collip considers two ways of regarding the phenomenon. Either the administered hormone and inhibitory substance are related as antigen and antibody, or else the inhibitory substance is a normal constituent of the blood which

is normally and physiologically balanced against the corresponding hormone so that it is masked. Collip takes the latter view and shows that it is borne out by clinical and laboratory experience. The repeated injection of hormone extracts will call forth the production of more and more inhibitory substances, so that each succeeding administration of hormone becomes proportionately less effective. There emerges from these considerations what Collip has called the "principle of inverse response"; this he defines as follows: "The responsiveness of an individual to administered hormone varies inversely with the hormone content or production of the individual's own gland." The author is careful to restrict his theory as yet to certain hormones. Nevertheless, it offers to over-energetic therapeutists a salutary warning of the need for caution in treating hypoglandular states, for the stimulation of the production of inhibitory bodies may defeat the very object sought for. The possibility of inhibitory sera in the treatment of hyperglandular states opens up a fascinating field of research. Particularly important will be the determination whether in any given functional endocrine imbalance we are dealing with an excess of inhibitory substance (hypoglandular state) or a failure to produce adequate amounts of inhibitory substance (hyperglandular state). No evidence is as yet available as to the nature of the antagonism of the inhibitory hormones, but it is clear that the sum of the constituents in the blood has not yet been reached.

ARTIFICIAL RADIOACTIVITY

During the last two years a series of remarkable discoveries has greatly changed the aspect of physical science. The growth of scientific knowledge is, of course, a connected process, and the new discoveries are an outcome of the direction of previous research. But the observer of the progress of physical science finds it easier to comprehend if he can recognize some outstanding points. One of these was the discovery of the neutron in 1932. Rutherford and his colleagues had searched for the neutron before 1920, and in his Bakerian Lecture of that year Rutherford forecast the properties of the neutron in one of the most remarkable passages in contemporary physics. Thus the idea of a neutron was not strange, but the recognition of its existence in 1932 had a stimulating effect on the imagination of scientists. Soon afterwards the electro-mechanical method of disintegrating atoms was discovered, and in America Anderson published the first experimental evidence for the existence of the positive electron. Then, early in 1934, M. and Mme Curie-Joliot demonstrated the possibility of manufacturing radioactive substances. This striking result arose out of their researches on methods of producing positive electrons. They found that when boron and other substances were bombarded with the swift alpha particles, or nuclei of helium atoms, emitted from the naturally radioactive substance polonium, they emitted positive electrons. The investigators were inspired to test whether the emission of the positive electrons from the boron continued after the polonium source of bom-

¹ Ann. Int. Med., July, 1934, p. 10.

bombarding particles had been removed. They found that the boron continued to emit positive electrons for a considerable period after the removal of the polonium, and that the number of positive electrons decreased with the time, according to the same law as that describing the decay of a radioactive substance. They concluded that atoms of boron had been transmuted by the bombarding particles from polonium into radioactive atoms. Chemical treatment of the boron showed that the radioactive atoms produced in it consisted of a form of nitrogen. They named this synthetic radioactive nitrogen "radio-nitrogen." A few weeks later, Cockcroft and Walton demonstrated that radio-nitrogen could be manufactured in their electrical apparatus by bombarding carbon with protons, or nuclei of hydrogen atoms. The production of a radioactive substance by shooting hydrogen atoms at a piece of carbon in an electrical apparatus is remarkable, as radioactivity is produced out of two of the commonest substances in nature, merely with the assistance of an electrical apparatus. These results provoke a multitude of ideas and suggestions. But some more details of the experiments must be appreciated before they can be seen in proper perspective. It is important to realize that the sort of radioactivity discovered by the Curie-Joliot is rather different from natural radioactivity. Their radio-nitrogen emits positive electrons when it disintegrates. Now natural radioactive substances emit wave radiations, the nuclei of helium atoms, and negative electrons. (Blackett and others have recently shown that some of the natural radioactive substances emit positive electrons, but in relatively small numbers.) No one as yet knows what the medical effects of rays consisting of positive electrons may be. So the old knowledge of the effect of radioactive rays may apply only partially to the new sort of radioactivity. Also, the Cockcroft and Walton apparatus, and similar machinery, is not as yet efficient in the physical sense; and it is far from being a commercially economical machine. Artificial radioactivity is only a few months old, and so far the chief results of its discovery lie in the stimulus to experimental research, and in the reformulations of the conceptions of the structure of matter. Following Rutherford's suggestion of 1920—that neutrons might be expected to penetrate the nuclei of atoms with special ease, and produce various transmutations—Professor Enrico Fermi of Rome has recently obtained spectacular experimental results. Physicists are particularly fascinated by this event, as Fermi, who is only 33 years of age, is considered to be among the leading half-dozen theoretical physicists in the world. His sudden appearance as a brilliant experimenter is dramatic. Fermi has found that the atoms of thirty or forty of the chemical elements can be transmuted into radioactive atoms by bombardment with neutrons. The wholesale character of the effect stretches the imagination beyond its normal limit. Fermi finds that heavy atoms as well as light atoms are transmuted. If uranium is bombarded with neutrons its atoms appear to be transmuted into atoms of an entirely new type. Fermi suggests that the new element has an atomic number of ninety-three. There is some chemical evidence that the atoms have the properties to be expected of an element of atomic number ninety-three. If this research is confirmed Fermi will be the first man, not to discover a chemical element, but to synthesize a new one.

X-RAY AND RADIUM PROTECTION

With the object of arresting the sequence of casualties to x-ray and radium workers, the British X-Ray and Radium Protection Committee was formed in 1921, as the result of joint action between the Royal Society of Medicine, the Röntgen Society, the British Association for the Advancement of Radiology and Physiotherapy (now the British Institute of Radiology, incorporated with the Röntgen Society), the Institute of Physics, the Radium Institute, London, and the National Physical Laboratory. The personnel of the committee was afterwards widened to include representatives from the provincial schools. The committee issued its first recommendations in July, 1921. Successive revised reports followed in December, 1923, and May, 1927. At the instance of the British committee, international recommendations for x-ray and radium protection were adopted at Stockholm in 1928 by the second International Congress of Radiology. These were largely based on the British proposals. The problem of adequate protection for the x-ray worker has been substantially eased by the introduction of the self-protected tube and more recently by the "shock-proof" tube and equipment. Account is taken of this in the latest (fourth) report of the British committee, which follows in the main the form of the international recommendations, and contains a number of changes and additions based on the experience of the committee and of the National Physical Laboratory in its inspection and testing work carried out in association with the committee. Copies of the report may be had from the honorary secretaries of the Protection Committee at 32, Welbeck Street, W.1, or the director, National Physical Laboratory, Teddington, Middlesex.

CHEST INJURIES AND PULMONARY TUBERCULOSIS

In view of the legislation providing for war pensions and workmen's compensation, the determination of the exact part played by trauma in the development of a relatively common disease like pulmonary tuberculosis assumes great practical importance. In a recent review of the subject N. N. Stoichitza¹ states that trauma as the direct cause of phthisis was considered not at all rare until quite modern times, but that owing to the absence of bacteriological confirmation all accounts dating anteriorly to 1882 must clearly be interpreted with caution. The Great War provided ample material for further study. It was shown that, in this connexion, two types of injury of the thorax had to be differentiated. Thus, penetrating wounds probably never gave rise to phthisis, perhaps because they generally involve important vessels and result in death within a short time. Non-fatal injuries of this type may, however, be followed by pulmonary tuberculosis after a long interval, and this is accounted for by lowering of the general resistance caused by continued suppuration and the prolonged stay in hospital. Contusions of the chest, on the other hand, are rarely directly responsible for the development of pulmonary tuberculosis. Stoichitza mentions the various theories put forward to explain the mechanism. The most logical explanation would appear to be as follows. The shock at the moment of impact causes reflex

¹ *Presse Méd.*, June 30th, 1934, p. 1051.

closure of the glottis, so that rupture of the distended lung tissue occurs at the level of the blow, causing haemoptysis immediately or soon afterwards. If this rupture takes place in the neighbourhood of a latent tuberculous focus (most commonly situated in the hilar region) the injured area provides an excellent breeding ground for the tubercle bacilli already present. To establish direct cause and effect in these cases certain conditions must be fulfilled. The patient should have been in good health before the accident, and an x-ray photograph taken immediately before or after must show no evidence of active tuberculous disease. Apyrexial haemoptysis, indicating rupture of lung, should have occurred immediately or soon after the injury, and there should be a continuity of symptoms from that time onwards. The tuberculous lesions, which are generally severe and of poor prognosis, should develop at the level of the injury and within six months at the most from the date of the accident. Still further to exclude the possibility of coincidence, the patient should not have been exposed to massive contagion or to conditions which may have so lowered his general resistance as to be in themselves the cause of endogenous reinfection. The author then describes two cases—that of a man, aged 57, who received a blow under the clavicle with a block of wood, and of another, aged 44, with a knife wound in the same region—which appear to have fulfilled these conditions: the evidence submitted indicates that in each patient the injury was the direct cause of the phthisis which followed. The paper does not deal with the possibility of aggravation by trauma of already existing disease—obviously a problem much more difficult of solution. But one important practical point emerges—the need, for record purposes, of a clinical and x-ray examination of the lungs (not merely of the ribs) immediately after an injury to the chest in all individuals in relation to whom the question of compensation may subsequently arise.

CLINICAL RESEARCH AT GUY'S HOSPITAL

The Governors of Guy's Hospital and the Governors of Guy's Hospital Medical School have accepted an invitation from the Medical Research Council to co-operate in the establishment of a new "unit" for scientific research work in clinical medicine. It has been agreed that the Council will provide the salary of a whole-time director and of his assistants, with the cost of all apparatus and research material used by the unit. For its part, the hospital will provide suitable laboratory accommodation free of charge, and will place and maintain beds at the disposal of the director: the latter is to be *ex officio* a member of the visiting staff, with a seat on the Medical Committee and the committees of the medical school. These arrangements are to be effective for a period of five years in the first instance. Dr. Ronald T. Grant, F.R.S., hitherto working in the service of the Council in the department of clinical research at University College Hospital, London, has been appointed director of the new unit. The invitation was issued to Guy's Hospital by the Medical Research Council in accordance with its general policy of improving the facilities available in this country for the scientific study of disease in the human subject, and, with this end in view, of increasing the number of

higher appointments for whole-time workers in this field. The financial resources the Council is able to apply to the purpose are those which were released when the senior post, formerly maintained by it at University College Hospital, and held by Sir Thomas Lewis, F.R.S., received permanent endowment through the generous action of the Rockefeller Foundation.

PROBLEMS OF DRUG ADDICTION

In his Norman Kerr Memorial Lecture last week on "Some International Aspects of the Problem of Drug Addiction," Sir Malcolm Delevingne began by drawing a distinction between the universal and the local forms of this evil. Practices such as opium smoking, the use of Indian hemp, coca-leaf chewing, and perhaps opium eating in India, are mainly confined to certain countries and races, and show no tendency to spread. These, though they have had significant international aspects in the past, are now matters of local rather than of general importance: the contrary is the case, because of their universality, with morphine, heroin, and cocaine addiction. From the international aspect, the newer addiction drugs (prominent examples of which are dicodid, eukodol, and dilaudid) may also be included in this category. Drug addiction, the lecturer insisted, is at bottom a matter of supply. The habit is facilitated and encouraged by drug traffickers, who are attracted by the enormous profits of this illicit trade. Hence the problem is not merely a national but an international one, because only by international co-operation can the machinations of the traffickers be defeated, and because all countries have the same problems to deal with in connexion with the causation, effects, and treatment of addiction. Sir Malcolm then proceeded to give an interesting sketch of the history of various efforts at international co-operation from 1921—when the League of Nations began the work entrusted to it, and the international obligations under the Hague Convention came into being—to the coming into full operation at the beginning of the present year of the Limitation Convention. As a result of these efforts the position to-day has improved greatly. There has been, during the past few years, a steady diminution in the amounts of morphine, heroin, and cocaine manufactured in the legitimate trade, while an efficient international machinery exists for the control over the export and import trade in these drugs. In the Permanent Central Board, in the Supervisory Body, and in the League's Advisory Committee a real international administration exists. Public opinion throughout the world has also been awakened as to the serious dangers of drug abuse, and interchange of information between various countries—especially as concerns the drug traffic—has been extended and made more effective. There is, however, a darker side, which forbids complacency. The illicit traffic still flourishes. Many individuals and gangs have been put out of action, but *primo avulso non deficit alter*! The situation in Europe, though not everywhere satisfactory, is clearing, but sinister development is on foot in the clandestine manufacture in the Far East. The recent production at low cost of morphine from poppy straw may call for

¹ The Fifteenth Norman Kerr Memorial Lecture of the Society for the Study of Inebriety, October 2nd, 1934. President, Dr. Humphry Rolleston, Bart.

careful study by the League. In conclusion, Sir Malcolm Delevingne indicated a number of questions which urgently needed solving; these, he contended, could only be satisfactorily dealt with by international co-operation. As examples of such problems he cited opium smoking, the treatment and "after-care" of addicts, the possibility of replacing heroin and cocaine by other drugs, the widely different consumptions of the different drugs in countries where conditions appear similar, and questions relating to the habit- or non-habit-forming properties of the newer narcotic drugs which are from time to time placed on the market.

TWO MEDICAL CENTENARIES

The British Medical Association, now in its 103rd year, and going so strong that it can jump 11,000 miles to Melbourne next summer for the Annual Meeting, looks with a benevolent eye upon the centenary festivals of younger medical bodies. To-day we print a brief account of the impressive ceremonies on October 4th and 5th with which the University of Durham College of Medicine, Newcastle-upon-Tyne, celebrated the hundredth anniversary of the founding of the Newcastle Medical School. A former Chairman of Council of our Association, Sir Robert Bolam, played a leading part in these ceremonies, and the Association was officially represented by the reigning Chairman of Council, Dr. Le Fleming. We publish also a historical note, by Dr. E. M. Brockbank, on the centenary of the Manchester Medical Society, and in this he refers to the exhibition which has been arranged as part of last week's commemorative proceedings to illustrate the history of medicine in Manchester. On that matter we would like to add one sentence, in praise of the valuable work of the author's son, Dr. William Brockbank, to whom is due much of the success of the exhibition now open at the Central Library, St. Peter's Square, Manchester.

A HEALTH EXHORTATION FROM SCOTLAND

Sir Godfrey Collins, M.P., Secretary of State for Scotland, spoke last week at Dumbarton, and devoted his remarks entirely to the importance of the local authorities of Scotland giving persistent attention to matters of health. He was probably speaking to the converted, but it was wise to indicate the need for consideration by those authorities of the evidence they wish to give before the recently appointed Departmental Committee on Scottish Health Services, and of preparation for action in the interests of public health when the report of that committee is published. Sir Godfrey Collins pointed out that in the sphere of health, as in that of economics, Scotland started out with certain initial advantages over some Continental countries, but that these countries were devoting very great attention just now to the health of youth and the cultivation of a healthy race, and so were rapidly overcoming the disadvantages of their initial lag. Our methods are not the same as theirs, and national characteristics are different; but neither the innate virtues of the Scottish race, nor the multiplicity of health services, nor the fact that there has been an immense improvement already in the health of the people, especially in the physique and well-being of the children, will suffice to maintain our advantage unless

all those responsible are constantly seeking to do even better. Sir Godfrey mentioned national mortality and tuberculosis as matters in which a further advance is particularly needed. All this is true, and probably the Scottish local authorities will gladly take the exhortation to heart. But Sir Godfrey cannot be allowed to claim Lord Lister as one of "the natural products of the Scottish race." He was born in Essex, came of Yorkshire stock, and received his medical education in London.

THE A B C OF BIBLIOGRAPHY

Though most journals have their own conventions in the matter of literary form and of references, and authors' preferences are suffered only within narrow limits, every writer on scientific topics ought to be familiar with the technique of bibliography. As formal instruction in this subject is rare, beginners must learn either from their mistakes or from occasional papers treating of this difficult art. A cordial welcome may therefore be extended to an important article entitled "The Principles of Bibliographical Citation" (*Bulletin of the Medical Library Association*, 1934, N.S. xxii, 183), from the pen of Dr. John F. Fulton, Sterling professor of physiology at Yale, who is well known to British readers as a distinguished historian and bibliographer. Described as "an informal discourse addressed to writers of scientific papers," it is full of sound advice and written in an engagingly light and humorous vein. Insisting that references should never be taken from a secondary source, the author quotes the laconic reply of President Routh of Magdalen College, Oxford, to a younger man asking for some precept which represented the experience of his long and scholarly career: "Always verify your references." Dr. Fulton has much that is wise to say on the question of footnotes, split dates in references, and pagination. His own preference is to draw attention to papers with useful and accurate bibliographies by putting in square brackets after the formal reference a short phrase like "exhaustive bibliography." "Once it has become a habit bibliography is never irksome." Yet its technique is sometimes far from simple if we remember that in the case of the thirty-one John Adamsons in the *General Catalogue of Printed Books* (British Museum, 1932, vol. 2) accuracy demands the inclusion of the dates of birth and death.

The Manchester Lloyd Roberts Lecture on "Medicine and the Further Evolution of Society" will be given by Professor F. A. E. Crew at the Royal Infirmary on Tuesday, November 6th, at 4.15 p.m.

The Prince of Wales will lay the foundation stone of the Birmingham Hospital Centre on Tuesday, October 23rd. The first instalment, for occupation three years hence, will provide 500 beds; when the whole scheme is completed there will be 740 beds in the main buildings, with 100 more in a separate wing for paying patients.

The veteran Italian surgeon Senator Francesco Durante, emeritus professor of clinical surgery in the Royal University of Rome, died on October 3rd, at the age of 90. He was elected an honorary Fellow of the Royal College of Surgeons of England in July, 1900.

MOTOR CARS FOR 1935

THE OLYMPIA SHOW

[FROM OUR MOTORING CORRESPONDENT]

Once again the time has come round for the annual inspection of the new models of cars which manufacturers are producing for the 1935 season. The Show, which is the twenty-eighth organized by the Society of Motor Manufacturers and Traders, opened its doors at Olympia on Thursday, October 11th, and will continue until Saturday, October 20th. Although there are fifty-four firms showing cars—six more than a year ago—a feature of the industry is the concentration of car manufacture into fewer but larger concerns, evidence of this being afforded by the fact that at the 1928 Show there were no fewer than ninety-eight car exhibitors. The international character of the exhibition is, however, again fully maintained, for in addition to about thirty concerns displaying British cars, twenty-four are showing foreign productions—that is, eleven American and Canadian, five French, an equal number of Italian, two Belgian, and one German. As during last year's exhibition, the car exhibits are located on the ground floor of the old Main Hall, while the special coach-builders' section will be found in the adjoining National Hall.

LOWER CAR TAXES IN 1935

When in his 1934-5 Budget the Chancellor of the Exchequer announced a reduction in the annual car tax of from £1 to 15s. per horse-power, to become operative on January 1st next, it was thought that this would lead British car manufacturers to pay more attention to cars with engines of greater horse-power than hitherto. So far, however, there appears, generally speaking, to be no marked tendency in this direction, for all the large British manufacturers appear to have decided that the lower taxes are more likely to result in a large increase in the number of users of small- and medium-power cars of from 7 to 15-h.p., and of an extension of the "two cars per family" movement, and that consequently there is more business to be done in these markets than is likely to arise from existing motorists purchasing cars of greater horse-power than hitherto. On the other hand, doubtless anticipating that the reduced taxes will induce a certain section of the motoring public to use vehicles of higher horse-power, there is a slight increase in the number of American cars displayed. By agreement between the members of the society, no announcements of new models were made before about the middle of August, but since that date the motoring press has revealed the main lines of the programmes of the principal makers. A new feature has made itself evident this year, that of a few makers announcing only part of their new models, having kept in reserve one or more "surprises" for the exhibition, reference to which, if they materialize, will be made later.

Price being an important matter in these difficult days, it may be said at once that while prices are higher in a few cases they are on the whole unchanged. Even, however, where the latter term applies, in view of the numerous detail improvements and added conveniences, cars, if not actually cheaper, are certainly "better value for money" than ever. As usual, the Show has an appeal to motorists of all classes—from those to whom the £100 car is attractive, as well in respect of cost as intended use, to the luxurious road Pullman, the price of which may be anything from £2,000 to £3,000. The plan of offering buyers a choice of cars with two sizes of engine at the same price appears to be meeting with increased favour. Thus the Austin Twelve can have either a 13.9-h.p. or 15.9-h.p. engine; the Standard Sixteen and one of the Hillman models offer the choice of a 16-h.p. or 20-h.p. engine; the Morris Oxford can be either 16-h.p. or 20-h.p.; and one of the Rileys 12-h.p. or 15-h.p.

MECHANICAL TENDENCIES

Though there are still many motorists interested in the technical characteristics of cars, it is probably true

to say that to-day the majority of car users are content to leave these matters to the manufacturers, taking it for granted that no maker will turn out cars which, mechanically, are not thoroughly up to date in design and construction. In other words, the majority of users to-day are mainly concerned with the questions of first cost, running expenses, good appearance, reliability, and durability. Despite this, it is perhaps useful at Show time to undertake a brief survey of the progress that is being made in chassis as well as in bodywork design and construction.

While vehicles with eight-cylinder engines are to be found on many of the foreign vehicles, in this country cars with engines having either four or six cylinders continue to share the popular favour, the relative position of the two varieties being approximately unchanged. It is interesting to note, however, that two well-known makers, although continuing their 10-h.p. four-cylinder cars, have introduced similar chassis and bodywork, but with six-cylinder engines, to meet the demands of those users prepared to pay a little more for the extra flexibility of the "six." The modern engine, whether with four or six cylinders, has reached a point, as regards both reliability and efficiency, which leaves little room for further improvement. Some "cleaning up" in the arrangement of the various engine adjuncts has, however, been effected, but otherwise there are no striking departures to record. What may be regarded as a reversion to old practice is the adoption by the Lanchester Company of engines having combined cylinders and heads, instead of the now usual method of constructing these separately. The reason given for the change is that there is less liability to cylinder distortion and wear, and that, with modern methods, the question of decarbonizing piston heads and combustion chambers offers no increased difficulty.

THE BATTLE OF THE GEARS

In the majority of cars the more normal form of change-speed gear is still employed, but it will be found that gearboxes of what are known as the synchromesh variety, which greatly facilitates easy and silent changing, have been more generally adopted. In the Alvis, Hillman, and Humber cars synchromesh is now provided for all four speeds, while in the Austins and Standards three of the four speeds are of the latest type. Free-wheel devices to facilitate gear-changing, so arranged that they can be put out of action when desired, are also being more widely adopted, being now found on Humber, Rover, Triumph and certain of the Standard cars.

The fluid flywheel transmission with preselective self-changing gear continues to be used on the B.S.A., Daimler, and Lanchester cars, the first-named feature in a modified form being now also found on some of the Singers. The self-changing gear has been used on the Armstrong-Siddeley cars since 1928, and is, of course, retained; it has also been adopted on the Crossleys, while it is being offered as an extra on the A.C., Sunbeam, and some of the Standard cars. An interesting innovation is seen in the Sunbeams and Talbots, this taking the form of a special clutch working in conjunction with the self-changing gear, the purpose being to reduce wear on the gear bands and provide smoother operation. An interesting new gearbox is also to be found on the 12-h.p. six-cylinder Wolseley "Hornet," this combining a normally used clutch and a self-changing gearbox giving three speeds in both forward and reverse directions. Those interested in the details of these new types of change-speed gears and other improved technical points of motor vehicles will be glad to know that a small portion of the exhibition is again being set apart for a display of working models by various manufacturers.

FRAME CONSTRUCTION AND SUSPENSION

Some new ideas in chassis frame construction are to be seen on the new Lanchester 18-h.p. and the Riley 1½-litre cars. The feature of the Lanchester is the addition of lattice steel welded to the inside of the frame members to provide greater torsional stiffness. In the Riley the frame members are of box section, while the usual

X-shaped cross members are replaced by a bracing of steel wire cable. Independent road wheel springing, which has become very popular in France and the United States (in which latter country it is known as "knee-action" springing), does not as yet appear to have caught on with British car designers, it being found only on one of the Alvis and Sunbeam models, and certain of the Singers.

A FRONT-WHEEL-DRIVE CAR

There have been rumours that, following a Continental lead, cars with front-wheel drive would be introduced by British makers. The only vehicle having this feature—and an interesting one it is, for it has, in addition, independent wheel springing and novel bodywork construction which obviates the use of the usual chassis—is the Citroën Twelve, which is of French design, but largely manufactured in this country. Other new models to which special attention may be drawn include, for those whose price limits are between £100 and £150, the remodelled Austin Seven and the new Morris Eight. For motorists looking for medium-priced cars with six-cylinder engines there are the Austin, B.S.A., Morris, Lanchester, and Vauxhall, while higher up the scale new vehicles are to be found in the 17-h.p. Armstrong-Siddeley and the 18-h.p. Lanchester, both having six-cylinder engines and self-changing gears, the 12/55-h.p. British Salomon, the Riley 1½-litre car, and the Triumph "Gloria" models.

Minor new tendencies to which attention may be drawn include the provision of twin wipers on windscreens for the convenience of the passenger as well as the driver, arrangements for carrying luggage and spare wheel out of sight, and the general adoption of flush-fitting direction indicators, now made so that, when used, they automatically fall after a few seconds. Although tyre troubles are no longer the bugbear they were in the early motoring days, a growing practice much appreciated by the owner-driver is that of providing cars with built-in jacks, this feature being now found, among other vehicles, on some of the Armstrong-Siddeley, Humber, Standard, Triumph, and Talbot cars. A useful feature which one would like to see more generally adopted is to be found on one of the Triumph models—namely, a steering wheel which is adjustable as to both height and angle to suit drivers of different stature; while yet another innovation worth copying is that of the rust-proofing of all exposed metal parts on the Rover chassis.

BODYWORK DESIGN

There were many who anticipated that, following the American, and to some extent the Continental, lead, British manufacturers would produce cars fitted with the "streamline" types of body. Actually, however, while bodywork in design and finish continues to show steady improvement, it will be found that British makers have, in the majority of cases, decided, "to make haste slowly," the only British car at the time of writing of ultra-streamline design being the Singer Eleven. From the scientific aspect it seems to be agreed that streamlining has no material effect on speed until from 40 to 60 m.p.h. is reached. At the same time it must be remembered that there are always those who prefer to purchase a car which embodies something out of the ordinary.

For general use the saloon type of car continues far and away the most popular, and while not of *outré* design, its lines are gradually becoming more flowing. There is also a marked tendency to give the fronts of cars a more "rakish" appearance by the use of sloping radiator guards. Attention may further be drawn to the improvements which are being made in the methods adopted for the ventilation of the interior of saloons and other covered cars, a point which will be appreciated by those who have to make long journeys. Although not of great interest to medical men, a section of the car exhibits which has a strong appeal to the younger generation of motorists of both sexes is that of sports models, examples of which are to be found on the M.G., Singer, Riley, and other stands. Despite their popularity in the United States, the fitting of wireless receiving sets on British cars has not made any great headway. Although there are several

sets on the market which can readily be installed, only two manufacturers—Hillman and Standard—include wireless-equipped cars in their programme.

AMONG THE ACCESSORIES

A feature of the accessory section of the Exhibition, which as usual is to be found mainly in the galleries, is the introduction of a number of devices specially intended to meet the new conditions set up by the latest motoring regulations—particularly in connexion with the order prohibiting the use of motor horns in built-up areas during the night. It has been quickly discovered that a good method for motorists to indicate their approach to a road crossing is momentarily to switch on the head-lights. To facilitate this one firm has introduced a new lamp operated by an "on-off" switch, which can be conveniently mounted on the steering column. When it is desired to travel after lighting-up time until 11:30 p.m. with the head-lights on, the normal switch lever is pushed over to, and left at, the "on" position. For night signalling purposes, however, the normal switch is placed at the "off" position, the head-lights being then momentarily switched on and off as desired by a push-button on the top of the switch, just in the same way as the electric horn is operated. Still another firm has introduced a switch which by a simple movement can be made to operate the horn during the permitted hours and the head-lights during the night! This question of the non-use of the horn during the night is arousing considerable discussion in motoring circles, especially as the law of the land still requires all cars to be fitted with a horn or other means of giving audible warning.

A tour of the accessory section is always worth while, for it will reveal many new adjuncts to a car that add to the comfort of motoring during the cold, wintry months. Also to be seen are some new preparations for addition to the radiators of motor vehicles to prevent freezing up during the extremely cold nights of the winter months. The ignition on practically all modern cars is effected by coil and distributor, but it is noteworthy that one or two new designs of magneto have been introduced which can readily be substituted for the existing ignition equipment.

In next week's issue it is proposed to follow the usual plan of referring to some of the new car models, more particularly those which are likely to appeal to the majority of medical men from the points of view of cost and suitability. Finally, it may be mentioned that the Show is open daily (except Sunday) from 10 a.m. to 10 p.m. On Tuesday, October 16th, and Thursday, October 18th, the charge for admission is 5s. up to 5 p.m., and 2s. 6d. after that time, the entrance fee on all other days being 2s. 6d.

C. J. W.

At a meeting of the Empire Social Services Group of the Royal Empire Society, Lady Denham outlined the work of leprosy relief and cure in British Guiana. There were some eight hundred lepers in hospital in British Guiana when she and Sir Edward Denham arrived; and many children—the home closed because of parents in hospital; or in whom disease had been either arrested or cured—were housed in the same building; and even taught by lepers. To combat this ethically and financially unsound method they decided to build a "home" for such children, and to segregate them. They had already collected £2,854 and had drained the colony dry, but £800 was still needed before the building could be put up on land provided by Government. Contributions should be sent to: Lady Denham's Home Fund (for Leprosy Children), c/o Lloyds Bank, Ltd., 222, Strand, W.C.2. Sir Leonard Rogers, in supporting, emphasized that "children were the key to the whole problem of leprosy," because children were most susceptible to the disease, and, further, approximately 95 per cent. of the cases could be cured if tackled in the early stages. In India, under Lord Reading as Viceroy, they had raised £150,000 and made a survey of two million people. Leprosy could be eliminated within a very few decades if tackled boldly and systematically, as envisaged by Lady Denham's scheme.

Scotland

Glasgow Housing and Health Exhibition

Opening the twelfth housing and health exhibition, promoted by Glasgow Corporation, Lord Provost A. B. Swan said that Glasgow had been criticized in the past for her housing conditions. The city's Housing Committee, however, had been as energetic as any other in Great Britain, and had tried to make improvements every year. It had also been said that there was a sameness about Glasgow's houses which was almost sordid in character: it must be remembered that the Corporation had to work within limits of cost, and to provide as many simple houses as possible. Under the Housing Acts since 1923 Glasgow Corporation had itself built 36,000 houses, and with help 48,488 up to the end of August, 1934; this was not a bad record. The Government was now trying not only to eliminate slums, but also overcrowding, and in certain types of houses on view in the exhibition suggestions were made for the solution of this problem. Other exhibits illustrated the most hygienic ways and the best labour-saving devices for the home.

Four model houses constitute the principal part of the exhibition. The all-Scottish house, built by the Scottish National Development Council, is of modern design based on the Scottish traditional form of domestic architecture, and to meet present-day requirements in sunshine and ventilation the horizontal casement window has been introduced. Another model comprises two flats of a modern five-story Vienna tenement, the structure being fireproof and vermin-proof, with skeleton frame of steel standard units and concrete floors. A novel feature is the provision of a garbage chute made of asbestos cement, with openings on every floor, which conveys household refuse to a portable receptacle on the ground level. The Housing Department of Glasgow Corporation exhibits three- and four-apartment flats similar to those the department is now erecting for the rehousing of people from overcrowded conditions. These houses are built of brick and finished in roughcast, the cost for the four-apartment house being £210, with a rent of 12s. per week, and the cost of the two-apartment house £270, with a rental of 10s. 6d. per week.

Laboratory of the Royal College of Physicians

Sir Robert Philip, in his annual report as curator of the Laboratory of the Royal College of Physicians of Edinburgh, comments on the increasing co-operation between this institution and various public bodies, such as the Department of Health for Scotland, the Home Office, and the Health Section of the League of Nations. At the request of the Committee on Scottish Health Services the specific death rate for that country was investigated, but it was considered advisable to extend the inquiry to include those of England and Wales and Sweden. Certain remarkable and unsuspected regularities emerged, leading to the following conclusions. (1) In England and Wales and in Scotland the improvement attained at any particular time in the death rates of the various age groups depends primarily upon the date of birth of the individuals concerned, and only indirectly upon the particular year under consideration. An exception was noted in the case of the infantile death rates, which showed definite lags in their dates of improvement. (2) These results were shown to be consistent with the hypothesis that the important factor from the point of view of the health of the individual during his whole life was his environment up to the age of about 15 years, and that improved conditions at later ages had little direct effect. Improved

conditions appear to have brought about beneficial results primarily through their action on the children. (3) It is suggested that improvement in infantile mortality is dependent in large measure on improvement in maternal health. This would explain why the infantile mortality rates lagged in their fall. (4) The figures for Sweden did not show the same simple regularities. It would appear that in that country a disturbing force began to operate about 1850, adversely affecting adolescents and young adults. The work is being continued, and the figures for Holland are being studied. Taken as a whole the fundamental conclusion is that the death rate is a product of two factors: one depends only on the age of the group considered, and is presumably essentially physiological in significance; the other depends only on the year of birth, and is taken to be characteristic of the environment during childhood. More intricate calculations indicate that there is likely to be in the future a very considerable increase of persons between the age of 65 and 85. In association with the Home Office, the inquiry into the relative toxicities of the solvents toluene and benzene was continued and completed. It appeared that the former was the less toxic, a fact attributable mainly to its lower volatility. The study has now been extended to include an investigation of the effects of ventilation upon the incidence of benzene poisoning in factories, the blood picture (aplastic anaemia and agranulocytosis) being employed as an index. Antirabic treatment was investigated for the League of Nations. No definite evidence was obtained that any one of the eleven methods was definitely superior, nor that live vaccines were more efficient immunizing agents than dead vaccines under the conditions, such as dosage, in which they were employed in practice. Sociological factors were found to bring about such divergencies in different countries as to render impossible any definite comparative evaluation of the different therapeutic procedures.

Health of Glasgow

The annual report by Dr. A. S. M. Macgregor, medical officer of health for Glasgow, shows that last year both the death rate and the birth rate in Glasgow were the lowest on record. The death rate was 13.4 per 1,000, as against 14.7 in 1932; this comparatively low figure is attributed to the good weather conditions during the greater part of the year. The estimated population of the city was 1,103,357, and the natural increase—that is, the excess of births over deaths during the year—was 6,614. As a result of housing operations the population showed considerable thinning out in the central wards of the city, with increases in the outer wards and in the adjacent county areas. The birth rate, 19.36 per 1,000, was only one-half of the rate prevailing fifty years ago. The infant mortality rate was 96 per 1,000 births, as compared with 112 for the previous year, and was the second lowest recorded for the city. This decrease was attributable to a low incidence of measles, whooping-cough, and pneumonia associated with the favourable weather, contributory causes being improved sanitation, housing, nutrition, and education. The principal feature in regard to infectious diseases was the continued high incidence of scarlet fever, the total number of cases registered being 8,373, which, however, was lower than the 9,158 cases for the previous year. Of the patients suffering from scarlet fever, 22 per cent. were not removed from their homes owing to pressure on hospital accommodation. The position with regard to the provision of institutional treatment for tuberculosis remained unaltered. Efforts were being made towards securing appropriate treatment for those who required it most. Improved housing conditions were now enabling isolation at home to be carried out

more successfully in the chronic case after preliminary treatment in a sanatorium or hospital. Another feature of considerable value was the judicious measure of rehousing of families in which there was a member suffering from open tuberculosis.

England and Wales

Healthy London

The health activities of the London County Council have been so closely followed from week to week in these columns that the section of the Council's report for 1933, by Sir Frederick Menzies, dealing with 'public health' contains little that has not already been published. The birth rate continues to fall; for 1933 it was the lowest yet recorded, being 13.2 per thousand, as against 14.3 in 1932. The number of births was more than 14,000 below that for 1918, when the influence of the European War on the birth rate was at its height. The infant mortality, however (54 per thousand births), was also the lowest on record. It is a little invidious to analyse these figures for different London boroughs, whose boundaries shade into one another, but taking the years 1930-2 and comparing them with the years 1921-3 one finds that while the infant mortality rate decreased almost everywhere in London it increased in five boroughs, and in one of them—namely, Paddington—the increase was as much as 19.7 per cent. In all the boroughs which show an increase in infant mortality—the others being the City of Westminster, Hampstead, St. Marylebone, and Holborn—the illegitimacy rate is excessive, being (except in Hampstead, where it is 9.4) over 11 per hundred total births. On the other hand, in Bermondsey, where infant mortality has declined by one-third in the course of ten years, the illegitimacy rate is the lowest in London (2.1 per hundred births). The deaths from measles, whooping-cough, scarlet fever, and diphtheria in 1933 were respectively 0.02, 0.08, 0.02, and 0.08 per thousand of population. Deaths from puerperal fever in London numbered ninety-six, and from other accidents of childbirth 119, the total maternal mortality rate being 3.66 per thousand live births. It is remarkable that for the six-year period 1928-33 maternal mortality was lowest in the East End boroughs—namely, Shoreditch, Bethnal Green, Stepney, and Poplar—and in St. Pancras and Lambeth, in all of which the rate was below 3 per thousand births. Leaving on one side the City of London, where cradles are scarce, the highest rates recorded were in Westminster (6.1), Stoke Newington (5.8), and St. Marylebone (5.2). The death rate (all causes) in 1933 in London was 12.5 per thousand living, slightly above the average of the last ten years, but forty years ago the rate was about 19. It has steadily fallen for all the principal infectious diseases and for tuberculosis, pneumonia, and other respiratory diseases, has fluctuated for influenza, and has risen for heart disease, cancer, and diabetes. The report contains much useful information about the multifarious powers and duties of the Council in connexion with common lodging houses, slum clearance, milk sampling, and the tuberculosis and venereal diseases schemes, and includes also the results of an inquiry made at the request of the Board of Control into the mentality of children, one or both of whose parents had been certified as mental defectives. The number of children examined was 617, representing 336 families. Of this number 2.1 per cent. were found to be supernormal, 51 per cent. normal, 31 per cent. retarded, and 15.9 per cent. mentally defective.

Cardiff Mental Hospital

The annual report for 1933 of the City of Cardiff Mental Hospital contains some statistics and notes of general interest. It is pointed out that while last year the percentage of voluntary admissions was the highest in the country, a further advance was recorded this year, the figure rising from 45.5 to 55.2. The percentage of admission of temporary patients also rose from 3.2 to 7; thus only 37.8 per cent. of the patients were admitted under certificates. The discharge rate also remained high, being 69.3 per cent., including those discharged as recovered or relieved. Of the patients discharged 70 per cent. had resided in the hospital for less than six months, and 26 per cent. left after a stay of less than two months. Factors which are believed to be shortening the stay of patients in this hospital are the granting of short leave of absence, the facilities for attendance at the out-patient clinic, and the activities of the social service department. Dr. P. K. McCowan, the medical superintendent, in his report states that in no circumstances is a voluntary patient certified at the institution; if such a patient insists on leaving when his mental condition necessitates continued observation arrangements are made for his transference to the local infirmary, where certification can be effected if necessary. In 1933 only two voluntary patients returned under certificate. On the male side a ward has been provided for voluntary patients only; this has been most welcome to the patients, who are reassured by learning that they will only be called upon to associate with voluntary patients' like themselves. Occupational therapy has proved most satisfactory. All sisters and male charge nurses continue to have a three months' course at the central classrooms, to enable them to supervise the daily classes held in the wards. The staff on each side consists of a head therapist with two assistants. In addition, on the female side there are four voluntary workers, whose services have proved very useful. During the year under review 277 females and 269 males passed through the classes. The average number of patients employed in useful tasks in the hospital, including the above, represent 78 per cent. of the male population, and 81 per cent. of the female. Classes in physical drill were restarted in 1933. While some improvement is manifest in the poorer type of patient, Dr. McCowan finds that the best results are obtained in the more educated, who have some genuine interest in the drill. The work of the out-patient clinic is also advancing, sessions being held twice each week. A routine ophthalmological examination has revealed interesting abnormalities in many instances, hypermetropia, with or without astigmatism, and presbyopia being notably common. Research work at this institution during 1933 included a study of infection of the nasal sinuses. Infection of the tonsils and nasal sinuses was found to be an important aetiological factor in a small minority of psychotics; its eradication in these cases led to cure or amelioration. Special emphasis is laid by Dr. McCowan on the connexion of these infections with the toxic exhaustive psychoses, where they appear to be comparatively common, and frequently causal factors. Another line of investigation revealed that a large proportion of the toxic symptoms accompanying prolonged somnifaine narcosis was due to disturbance of the carbohydrate metabolism of the liver and heart by the narcotic, resulting in ketosis, tachycardia, fall of blood pressure, and varying degrees of circulatory collapse. These symptoms could be largely obviated by the administration of insulin and glucose as an integral part of the narcotic treatment. Carotene was found to be effective in increasing the weight of patients convalescing from manic-depressive or confusional attacks, there being a corresponding improvement in the mental and physical conditions. An exceptionally high percentage of reactors to the tuberculin test

was discovered, and it is thought that among the patients there may be a certain number of open cases of the relatively chronic and symptomless type. A systematic investigation has been instituted in conjunction with the tuberculosis department of the Welsh National School of Medicine. The patients were for the most part old-standing cases of dementia praecox, and Dr. McCowan thinks this fact may be at least as important as questions of environment, for there is undoubtedly a close relation between the two diseases, possibly even of a hereditary nature.

The Radium Institute, London

The annual report of the Radium Institute (London) for 1933 continues to record satisfactory progress, and research work on massive dosage (radium beam therapy) from a unit of 5 grams of radium is in progress. A considerable number of beds have been allocated for this purpose, and, as they were previously used for the reception of paying patients, this public-spirited action has entailed considerable financial sacrifice. A high-voltage x-ray outfit has been installed at the Mount Vernon Hospital, Northwood, and will enable important research and therapeutic work to be carried out there. The medical report, which is drawn up by Drs. Roy Ward and Durden Smith, contains a valuable summary of past and present work, mainly arranged in tabular form. During the year contributions to the literature of the subject have been made by Dr. Roy Ward on the clinical side and by Dr. J. C. Mottram, the director of pathological research, on more purely scientific matters.

Nutrition of School Children in Hull

In the school medical service section of the annual report for 1933 of the City and County of Kingston-upon-Hull Dr. Nicolas Gebbie, medical officer of health, points out that, while there is a great deal of discussion at present about malnutrition among school children, the assessment of degrees of nutrition is difficult in the case of the individual, and even impracticable on a large scale. Statistical information based on average weights and heights is of little value, for well-nourished children may be below the average in weight and under-nourished children may be above it. Even an individual assessment after careful medical examination is fallible, and does not lead very far, for malnutrition may be due to such different factors as insufficiency or unsuitability of food, inability to assimilate fully the food which is eaten, and insufficiency of sleep, exercise, or fresh air. Errors of diet appear to be most common in children well above the poverty line, the child being allowed to choose the food it prefers, and to eat at irregular intervals. An investigation of the position as regards meals and sleep was made in May, 1933, in the children attending the open-air school in Hull, among whom there are many cases of malnutrition, due to various causes. These children received half a pint of milk on arrival at the school, and a substantial midday meal, which most of them enjoyed. No other food was allowed. The children returned home about 5 p.m. It was found that no fewer than 178 had two meals between then and bedtime, while ninety-nine had one meal. Most children from the age of 8 upwards went to bed between 8 and 10 p.m. This investigation arose from the discovery that many children came to the ordinary schools in the mornings without having had any breakfast, or very little, the reason being lack of appetite. In many cases it was clear that the child had got into a "vicious circle," having had the last meal of the day, and often an unsuitable one, at 8 or 9 p.m. As a result there was a condition of subacute gastritis, with the usual loss of appetite. Since the child had had no breakfast, the mother sent it to school with a most unsatisfactory

lunch to be eaten about 11 a.m. This prevented justice being done to the midday meal, which would probably have provided more satisfactory nutrition. The child becomes hungry about 4 p.m., and receives a meal on getting home. After this he plays for several hours, becomes hungry again, and receives another meal about 9 p.m. There is no doubt, the report continues, that it would be advantageous for children to receive only one substantial meal between their arrival home and going to bed, and for bedtime to be earlier in most cases. As one result of this investigation all children on entering the open-air school are supplied with a leaflet for their parents, which stresses the importance of regularity in the taking of food and of sufficiency of sleep. Dr. Gebbie reports that while ringworm on the scalp has reached the lowest level of incidence on record, and can possibly fall no further, scabies is far too prevalent. Inefficient home treatment with sulphur is cited as one of the causes, the parents not realizing the need for medical supervision to ensure the treatment of contacts and the full cleansing of clothing and beds. Reinfection is common. It is also noted that many parents have contended that the cost of transport of the whole family in these cases to the corporation sulphur baths is too high. An appeal is made in the report for a fully staffed child guidance clinic on a comprehensive basis, with home visitors specially trained in psychological work.

Estuary Muds at Southend-on-Sea

A small establishment for "medicinal mud baths" was opened by Councillor H. E. Frith, the mayor of Southend, on October 2nd. This venture is due to the initiative of Dr. Mary Nicol, who has made some study of the medical uses of estuary muds in Germany. The mineral analysis of the "schlick" at Wilhelmshaven and that of the Thames estuary appear to be similar, both being very rich in silica (60 per cent.), and in aluminium oxide and iron. The organic content and the biological properties of these muds have not yet been investigated. These marine deposits have a general resemblance to those of the well-known "limans" of the Crimea, which are now very largely used for rheumatism and other diseases, both in the fresh state on the coast and when dried and transported to the cities, especially for use in the winter months. At a reception in the Clifton Hotel, with Dr. J. F. Walker in the chair, Dr. Fortescue Fox in a short address congratulated the town of Southend and Dr. Nicol on the first attempt to organize the medical use of estuary muds in England. Southend, he said, had special advantages as a London health resort on the "Thames Riviera," with the east-and-south climate, which was very favourable to health, and especially to the fundamental function of breathing. The place possessed three good elements in its shelter and saltings, and a sunny and southern aspect, and also had the driest winter climate in Britain. There was great need for small treatment centres at the great holiday resorts, where natural remedies (air, light, heat, water, the peloids or natural semi-solid media and movement) could be scientifically applied under medical direction. Not all holiday makers were quite well, and their time at the seaside gave them a chance for some simple recuperative treatment, which might prevent many serious diseases and breakdown. Such a centre would be a boon to ailing people all the year round at Southend, but especially in the months of winter and spring. Those who were subject to catarrh and feeble circulation and to many nervous and rheumatic affections would all certainly benefit from a properly organized establishment. Dr. Nicol had done wisely in including not only the estuary mud, but also local arm and leg baths and tonic aerated hot sea-water baths in her scheme.

Reports of Societies

"MEDICINE AND MORALS"

LORD HORDER'S ADDRESS

The annual general meeting of the Medical Society of London was held on October 8th, the routine business being followed immediately by the address from the chair of the incoming president, Lord HORDER OF ASHFORD. The title given to the address was "Medicine and Morals."

Lord Horder began with the admission that the title had a certain spurious piquancy. The word "morals" had become closely attached to certain aspects of social behaviour, but he employed the word in an older and wider sense, meaning the sum of the criteria governing human conduct and thought at the time being—a kind of design for living, a pattern which it was considered well to follow, whether for the individual or for social groups. Morals in this sense must have begun very early in human history, and they had been constantly changing—in some eras slowly, in others swiftly. The pattern for the individual changed more quickly—and therefore sometimes more catastrophically—than for society in general, a circumstance which was fortunate for society. The individual could even afford to say, "I have no morals" (though by that admission he declared his morals, which were, in effect, that he was a law unto himself), but society could never be without morals, because in that event it would cease to exist. If morals were an art only, and not both an art and a science, no doubt the pattern of life would remain much the same for generations together, as, indeed, it did before science began. But science was born at last, though the travail was long, and with the birth of science medicine for the first time became a living thing.

THE PHYSICIAN AS THE NEW PRIEST

Medicine as an art, of course, was ancient. Yet if the litter of superstition and dogma which encumbered it even up to Harvey's time were swept away there was really very little left that could be called an art. Hippocrates laid down some excellent basic principles, but for two thousand years no edifice was built upon his foundation, for the simple reason that the bricks and mortar of science did not exist. Medicine, during all this time, enjoyed the companionship only of philosophy—a barren alliance so far as the patient was concerned, for he could get his mental comfort from the priest or from humanistic teachers, whereas for his body the physician had very little to offer him.

At first slowly, in face of opposition, and then more rapidly, as the new criteria became irresistible, science changed the pattern of life. It also activated medicine, which made life longer and better worth living. Men began to take control of life themselves, until to-day the danger was, not that they should be cramped by authority, but that they should be fatigued or even destroyed by their own freedom. Realizing that the causes of their unhappiness, as of their physical ills, lay in the biological sphere, they sought the physician rather than the priest. Bewildered by the prospect which their liberty opened out, and all unaccustomed to deal with the raw material of their natures as now revealed to them, they went to the doctor for guidance. To them he was the realist, the link between the fine abstraction which still beckoned and the particular application for which they still hoped. "He that sinneth before his Maker, let him fall into the hands of the physician." Why? Because to the physician the individual was not a metaphysical constant, but a physical variable, and this outlook enabled him to lift up many a weary head and comfort many a sorrowing heart. The patient might well go too far along the road of scientific economy, and place his trouble in a lower category than that to which it rightly belonged. It might be the loss of his aspirations and ideals from which he was suffering, not a mere failure to adjust his physiological or psychological balance, and thus the doctor must act as priest as well as physician.

It was an advantage, at any rate, that in these days the cards were on the table. Thirty years ago Maudsley complained of the hypocrisy which led people to condemn the plain speaking of their ancestors and practise a decent concealment of their sensualities. Were Maudsley living to-day he might be surprised at the frankness with which patients spoke on matters on which the patients of a former day were reticent—a frankness not always free from a suspicion of relish. Clifford Allbutt once said that there was as much harm done by talking about things as by suppressing things, and that to familiarize evil was to tolerate it, and Lord Horder considered the sentiment appropriate to much that happened in the consulting room, and that there was something psychopathic about the glib way in which some patients described their sex life.

THE PROBLEM OF BIRTH CONTROL

Entering the arena of social morals, where, he said, on some issues it behoved medicine to take a guiding hand, while with regard to others it was more appropriate that society should lead, medicine answering pertinent questions, and being prepared to give practical help, he spoke first on the subject of birth control. Here, in spite of the fact that lay interest and inquiry were both awake and pressing on this subject, medical opinion was strangely discordant and ill formed. The majority of medical men and women still began practice with no instruction in contraceptive methods—a startling anachronism when it was remembered that memorandums had been issued to public authorities by the Ministry of Health encouraging the formation of clinics and the giving of medical help to women when contraception was desirable for saving life or preserving health. In private practice patients not seldom complained that their doctors failed to give them the practical help they had a right to expect. This failure to help was not due to the doctor holding views that ran counter to the principle at stake, but to ignorance of methods and technique applicable to particular cases. The defect should be remedied without delay. It would be lamentable if the moral fabric of society became definitely formed in this matter, while medicine failed to give the guidance which it alone could give. Was it that medicine itself offered a resistance because it was still influenced by a certain body of religious doctrine? Or was it thought that such help might encourage extramarital sex relations? That pregnancy should be regarded as the chief or only deterrent to illicit intercourse was a terrible indictment against individual idealism on the one hand, and the aims of social reform on the other. Morality based upon fear of penalties was entirely a static affair, though doubtless of service at the beginning of human progress. Surely society was ready for a harder lesson than that. Increased control in the sphere of sex, like increased control elsewhere, was an inevitable result of the ceaseless probings of science, and that such increased control might be used for ill as well as good was a general, and not a particular, result of social development. Perhaps the profession was still awaiting the mandate of a completely convinced society. It ought not so to wait. It ought to be ready, with the fullest assistance so far provided by medical science, to answer in practical and positive fashion the questions put by those who, having emerged themselves from the thralldom of sex dominance, honestly and sincerely sought such expert help.

Inability to deal constructively with birth control brought in its wake the nemesis of the social evil of abortion. Here was another matter which cried out for full examination and advice. The anomaly which allowed the well-to-do to get rid of the unwanted child before it was born, without danger to life or reputation, yet denied such relief to the poor, was a stigma to which society was at last awakening.

EUTHANASIA

The subject of euthanasia was an old and recurring one, and more was likely to be heard of it in the immediate future. To many who discussed it the problem seemed simple, but to those who were brought into daily contact with the facts there was no problem more difficult.

Whose life should be terminated? And by whose decision? At what level of congenital defect, physical or mental, should the line be drawn? What diseases were to be regarded as incurable, and at what stages in them should the cup of Lethe be drunk? Was the patient's judgement to be relied upon, warped as it often was, whether by the malady or the treatment? How could it be known that his mood was permanent? How was the calculated decision of a man's intelligence to be distinguished from the cry of strained emotion for relief? It had to be recognized that the request to end suffering by ending life was not always the cry of a spirit stricken past endurance, but rather the dramatic demand of someone whose patience, never too good, was now exhausted. Finally, when the demand to end life was made on behalf of someone else, it was often not the patient, but the patient's friends who could not stand the strain. "Doctor, you must end this agony!" said a woman to him recently, and his reply, "Do you mean yours or your husband's?" brought home to her, rather sharply, the real position. The inalienable right of another person to live, if he so desired, had been entirely forgotten. "I am sure he does not want to live" might well mean, "I do not think I can possibly see him suffering any longer."

These were some of the considerations which must be advanced when they as medical men were approached by laymen who believed that the institution of euthanasia of the direct kind would be of benefit to humanity. In his judgement, this was the one subject upon which, though their experience should be available to guide the decisions of others, they ought not to express strong views. Their whole training and outlook were directed towards the prolongation of life and the relief of pain, and while they had to distinguish prolongation of life from prolongation of the act of dying, he thought the larger decision should be left to the developing good sense and judgement of the community, whose servants in such a matter they really were.

DUTY OF MEDICINE TO SOCIETY

After the briefest reference to other matters, including voluntary sterilization—the Brock report deserved the most careful study—the drink problem, food problems, industrial fatigue, and the campaign against unnecessary noise, Lord Horder went on to deprecate any aloofness of medicine from questions that affected social groups or society in general, and ultimately determined the general welfare and happiness. Morals, in the sense in which he had used the term, were constantly changing, and medicine could guide or even to some extent control those elements in the mosaic which concerned its own art and science, or it could remain detached and let society take care of itself. If, as he thought desirable, and indeed incumbent, the former alternative were adopted, then it was essential that the examination of these elements and guidance concerning them should be undertaken by representative bodies in medicine, rather than merely by individuals. Pooled opinion was much more useful than the expression of personal views. Moreover, the limitations imposed upon the individual by the traditions of medicine were severe, and rightly so. In the first place, no amount of publicity of itself conferred prestige upon the doctor, though it was perhaps wise to admit in these days that prestige could not be attained without some degree of publicity. Again, no medical man, however expert in his own sphere, could take upon himself the responsibility of standing for the general body of medical opinion; indeed, in respect of the things he had been considering, the very fact that a man was an expert might be a danger.

It was to his colleagues assembled in council that the individual, stirred to a protest or eager for a reform, should address himself in the first instance. Convinced himself, he was not likely to fail in convincing them if his case was a good one. He could thus secure the powerful aid of their corporate influence. So it should be with matters submitted by various sections of the public or by Government—for even Government sometimes, and quite sincerely, sought the way of salvation:

it was to representative and authoritative bodies inside medicine, and not to individuals, that these inquiries should be directed. But where were the representative and authoritative bodies? The Society he was addressing, like its vigorous offshoot, the Royal Society of Medicine, existed for academic discussions. The British Medical Association was a body most admirably suited to guard the status and amenities of its vast membership, but this function being apparent and accepted, it was reasonable that it should be suspect when matters of public interest were being ventilated. It was true that in the last analysis the public interest and the interest of the doctors were identical, but this last analysis must not be assumed as being made by those who were vitally concerned in the direction of social morals. Some would say that this was the sort of thing that might be adequately undertaken by certain health societies which had on their committees both doctors and laymen. But in the discussion of medical topics he distrusted such mixed bodies thoroughly. How could people confer with any expectation of a helpful issue if they did not speak the same language? There remained the Colleges, strong and representative bodies. Together the Colleges might voice a solidarity of opinion on any question arising within their walls or submitted to them from outside, and no impeachment on the ground of bias or parochialism could possibly be advanced. Against the Royal College of Physicians there was formerly lodged the reproach that it isolated itself from important outside affairs which cried aloud for the guidance of medicine, and the stigma was not unmerited. The present President of the College (Lord Dawson of Penn) was to be congratulated upon the efforts he had made to remove that reproach. His invitation to discuss certain matters of general interest to the public in comitia showed that he was alive to one of the chief functions of the College, and the setting up of a committee whose sole reference was to keep the College in touch with outside affairs which had medical bearings was a most laudable action. The recent decision of the Presidents of the two older Colleges to discuss disciplinary matters and penal cases in joint council was an advance in another and equally important direction. Whilst individually the Colleges were strong, they would more than treble their strength and their public influence if there were a closer liaison between them. Indeed, apart from acting in concert concerning examinations, the liaison scarcely existed. At present there were risks of divergence of opinion, and there was duplication of discussion. A closer union was much to be desired. Lord Horder closed by suggesting the idea of an Academy of Medicine in this country, of which the Colleges would be the main pillars. He again quoted Clifford Allbutt: "If a social discipline and fruition are to be renewed and enlarged, it must be upon a new synthesis as laborious and ardent as the former, and more true. . . . Swiftess and strength come of union of wills and singleness of heart rather than of wisdom."

At the close of the address a vote of thanks to Lord Horder was carried on the proposition of Mr. WARREN Low, seconded by Dr. WALTER CARR. Earlier in the evening the Society had taken leave of its retiring president, Sir John Thomson-Walker, to whom also a vote of thanks was passed. Some handsome new seating accommodation in the meeting room is Sir John Thomson-Walker's gift to the Society to mark his year of presidency.

F. Deak (*Thèse de Paris*, 1934, No. 535) states that in contrast with other districts in Rumania, in the delta of the Danube malaria is insignificant both in number and in gravity. The explanation for its infrequency is to be found partly in the preference shown by the anophelis for the cattle and partly in a relative immunity, combined with an excellent general condition of the population. The eastern part is almost entirely free from the disease, the average endemic incidence sometimes not exceeding 0.4 per cent. among 2,000 children up to the age of 15, as compared with 14 per cent. in the Tulcea area, at the apex of the delta.

CORRESPONDENCE

Publicity

SIR,—From time to time you publish in your correspondence columns and elsewhere indignant protests from practitioners whose articles have been quoted by the lay press, and who wish to repudiate any responsibility for their appearance. I wonder if there is any advantage in such disclaimers. Those who are familiar with the professional status of their colleagues require no such assurance. Others acquainted with the methods of journalism are perfectly well aware that no precautions can prevent these occurrences. And a tiny minority who might be willing to accuse your correspondents of seeking publicity or notoriety may even interpret the disclaimer as corroboration of the original intention! In any case nothing can prevent the lay journals from quoting from your columns, extracting the relatively dramatic, and unhappily, on occasion, misquoting and misrepresenting. For the author of the original article to protest is obviously useless. Is it too much to say that not only is it useless but it is quite unnecessary?

There is another aspect of this subject to which reference may not be inappropriate. The interests of medical men are not by any means restricted to their professional life, and there are certain outside activities upon which they are, rightly or wrongly, regarded as authorities, and upon which their opinion is considered to be correspondingly desirable. From their familiar association with the use of the telephone doctors are particularly fair game for attack through this convenient but highly dangerous medium. And once your ear is at the instrument and your arrival admitted, and you are inveigled into saying something, no matter what, the mischief is done. If, good-naturedly, you believe you may be doing a service to the public—and that really is the motive on most occasions—publicity is inevitable. The most fervent request to withhold your name is unlikely to be respected, since any news value attaching to the opinion of one who is being represented to be an authority depends entirely upon his name being mentioned. Alternatively, a curt refusal may rebound upon you to your subsequent discomfiture, and those who have once suffered in this way have learnt that it pays to be courteous.

At midnight a few weeks ago the news editor of one of the daily papers felt unable to rest until he had telephoned to take my opinion upon a "story" just to hand from South Africa: an indignant protest against holding Olympic Games for women because there was abundant evidence that some men had actually competed. It says something for my forbearance that my only observation, even at this hour, was that I knew absolutely nothing about it. Yet this became ingeniously interpreted as an authoritative denial of the rumour. A week later—again at the (apparently critical) hour of midnight—I was approached by another journal in reference to an inquest that had been held that afternoon, at which the coroner had expressed his opinion that the suicide of some unhappy young man was due to his "having lived too strenuously." "Did I think the coroner was right?" and "What did I suppose the coroner meant?"

It may be that some of us might succeed in fencing ourselves round by a complete secretarial inaccessibility (more appropriate, perhaps, to a Pope than to a medical man), and thus receive adequate protection from telephonic assault. But by the time we had acquired an eminence commensurate with such a state we should be "in the news" anyway.—I am, etc.,

London, W., Oct. 8th.

ADOLPHE ABRAHAMS.

Is High Blood Pressure a Risk?

SIR,—In your issue of August 25th "M.S., F.R.C.S." appears to call for a review of the vast amount of work written on high blood pressure. The cases to which he makes reference appear to cast a cynical doubt on the now recognized fact that, as a rule, high blood pressure certainly carries with it a risk which, to our shame it must be admitted, has been seriously overlooked since Clifford Allbutt drew attention to this disorder. The condition, according to Fahr, claims 10,000,000 afflicted in America, and 200,000 deaths a year—an incidence as common as cancer and tuberculosis together; according to Parkinson it is a "very common disease, which is responsible for so much suffering and mortality in late middle life and early old age." I can endorse Parkinson's observations even more strongly from my experience in this country, where the ravages of rheumatic fever are not so prevalent as in the West, and therefore show up hypertensive failures more readily.

One is tempted to ask: Has "M.S., F.R.C.S." met no other cases of high blood pressure? If he has not he is an extremely lucky medical man. If he has met many cases with such high systolic pressures, surely there must have been many with serious complications. I have had several friends and many patients with diastolic pressures of 170; very few indeed are alive. I have seen four cases which had systolic pressures of over 300. These could not be recorded, as the manometer only read up to this figure. The diastolic pressures in them were over 160. All these patients were over 60 years of age, and until a short time prior to a fatal issue had nothing more than the mildest general symptoms. One patient of mine, 68 years old, apparently in good health, had a systolic pressure of 210 and a diastolic of 95; another, a lady, a systolic of 300 and a diastolic of 90. These striking exceptions, and many more like them, have not made me cease to believe that high blood pressure, particularly when it occurs under 50 years of age and once any symptoms are manifested, is a danger to life of which some kind of notice should be taken.

An account of the numerous strokes which appear in these cases is given in my Sir Charles Hastings prize essay on "The Stroke in High Blood Pressure," published in the *British Medical Journal* of January 30th, 1932.—I am, etc.,

General Hospital, Colombo,
Ceylon, Sept. 22nd.

Preliminary Ligature in Toxic Goitre

SIR,—The correspondence concerning preliminary ligature in toxic goitre has probably continued long enough for adequate ventilation of the different opinions that are held. An excellent summary of the position was supplied in your issue of September 29th by Sir W. I. de Courcy Wheeler. I cannot, however, remain silent in view of the repetition by Mr. G. Bankoff in your last issue of the astonishing and dangerous fallacy that the degree of the reaction depends, not on the amount of thyroid tissue that is removed, but on how much is left behind. If this were true, the only logical inference would be that the lowest mortality rate would be obtained by performing a total thyroidectomy in all the worst cases. This is contrary to clinical experience, and the principle would be most dangerous if generally applied. I fully agree with Mr. Hawe and Mr. Bankoff that "for the good success of the operation it is imperative to remove at least three-quarters of the gland," and in fact I frequently remove more than this. In the great majority of patients it can be done in one operation, but in a

small minority it must be done in stages. The patient's reaction depends, in my opinion, on the amount of disturbance to which she is subjected, and that is why operation in stages, including preliminary ligature, is occasionally necessary. This procedure is reserved for those patients who are most seriously ill, so that it is no matter of surprise if sometimes one of them dies as the result even of the most cautious surgery. In some clinics patients who are as ill as this are not subjected to surgery at all, and perhaps some in consequence die who might have been saved. Their deaths then appear, however, in medical, not surgical, statistics. Unless we are shown both sides of the picture our data are really incomplete.—I am, etc.,

London, Oct. 8th.

Female "Bleeders"

SIR,—The case of a female bleeder recorded by Drs. M. A. Foulis and J. W. Crawford in the *Journal* of September 29th (p. 594) prompts me to send you the genealogical tree of a very similar family, most of whom live in this town. I cannot trace it back any further than the grandmother of the present family, who is assumed by her descendants to have been a bleeder because she died from uterine haemorrhage the day after giving birth to the twins shown. I have put a star against three

members of the tree, because I have been unable to find out whether they are bleeders or not. One of these died as a child of 12, one lives far away, and the third, a sturdy boy of 14 months, has so far been preserved from cuts and scratches. My partner, Dr. Mary MacLaren, attended the eldest daughter at her confinement last year. She had previously dosed her liberally with calcium gluconate and laevulinate, and informs me that at the confinement there was a rather profuse loss, followed by a more severe haemorrhage three days later. Otherwise the women did well. One of her sisters had a very troublesome appendix two years ago. This we removed without untoward incident after a preliminary intensive treatment with calcium gluconate and a dose of haemoplastin.

The bleeding in this family is of a severe character. All the members marked with black dots suffer from fairly frequent epistaxis, which may last for several days. A cut or a tooth socket seldom stops bleeding within twenty-four hours, and several times haemorrhage has kept on for a full week. I cannot give the clotting time for the blood, partly because I seldom treat the family, and partly because the only attempt I have made to time it failed. The blood seemed to be quite fluid after standing for an hour, and then I had to leave it. My own blood, which I had put up as a control, had clotted within three minutes. According to the mother's statement the bleeding in her four children started in infancy. She makes a curious statement about her eldest daughter to the effect that she bled from the mouth about the same time every month until she was 2. While this is difficult to believe, she says that the periodicity was so marked that she could not mistake it.

The family tree I give is unfortunately very small, but, such as it is, it shows conclusively that in this family at least bleeding is not a sex-linked character, and suggests that it is almost a Mendelian dominant.—I am, etc.,

Winford, Cheshire, Oct. 6th.

W. N. LEAK.

Evipan on a Full Stomach

SIR,—With reference to the point raised by Dr. Langton Hewer, commenting on our recent paper on evipan anaesthesia, we entirely agree with him that the administration of evipan or any general anaesthetic when the stomach is overloaded may be a dangerous procedure.

We do not consider that any suggestion to the contrary was either made or implied in our article. Our statement was: "Evipan may be given without danger on a partially full stomach." In such circumstances, in a healthy subject the danger of syncope is remote, and, owing to the nature of the anaesthesia, there is practically no risk of stomach contents entering the respiratory passages. In the example quoted the patient had taken a light tea only, and had the wording of the text been "the patient recently had a light meal" instead of "the patient recently had a meal," perhaps our meaning would have been more evident.—We are, etc.,

Royal Westminster Ophthalmic
Hospital, W.C.2, Oct. 5th.

T. KEITH LYLE.

F. G. FENTON.

Control of Haemorrhage in Prostatectomy

SIR,—One serious complication of endoscopic resection of the prostate is haemorrhage and clot retention in the bladder. The haemorrhage cannot always be arrested by diathermy and fulguration at the time of the operation, nor can it always be controlled by the pressure of a retained large catheter. Irrigation with silver nitrate merely converts a soft clot in the bladder into a hard one, which often necessitates an open operation for its removal. To obviate the disadvantage of haemorrhage and clots I have recently in all cases tied in two catheters, one large and one small. Continuous irrigation is given, the inlet being the smaller catheter. The fluid used is 5 per cent. sodium citrate. This prevents clotting, and the catheters are seldom required after forty-eight hours. Instead of two separate catheters a double-channel catheter may be used. These are made by the Genito-Urinary Manufacturing Company. I strongly advise continuous irrigation as the initial after-treatment following endoscopic resection of the prostate.—I am, etc.,

London, W.1, Oct. 2nd.

F. MCG. LOUGHNAME.

Traumatic Rupture of the Lungs

SIR,—Dr. W. E. Cooke's paper (*Journal*, October 6th, p. 629) on traumatic rupture of the lungs without signs of trauma of the chest wall is of great interest to me, as it recalls a case which occurred in my own practice some years ago, and which has been puzzling me ever since. In the Southern Argentine, where I practised for a few years before the war, I was called one morning to see a policeman who had just been brought down from the country, having been in a rough-and-tumble the evening before with some prisoners he was escorting to the coast. When I saw him he was in a very serious condition, and I found on examination that there was an incised wound on the right chest in the mid-axillary line. There was complete dullness from the right clavicle downwards, and all the signs of a serious right haemothorax. I went back to my house to fetch some instruments, meaning to do a preliminary aspiration, but when I returned soon afterwards the man was dead. I did a necropsy by order of the local judge, and was surprised to find that, first, the wound had never penetrated the chest wall; secondly, that the ribs and the parietal pleura were perfectly intact; and, thirdly, that the whole of the right pleural cavity was filled with blood and broken lung debris. Nothing of the right lung remained except

a torn, jagged root; all the lung substance proper had vanished. The left lung, heart, and abdominal viscerae were intact.—I am, etc.,

Kirk Michael, Isle of Man, Oct. 9th.

E. G. FENTON.

Tuberculin

SIR,—A letter published in your issue of September 29th (p. 612), by "M.B., D.P.H.," is a most valuable and interesting human document. Might I suggest that this doctor reads an article written by Dr. J. R. Gillespie, tuberculosis officer for County Down, and published in the *Ulster Medical Society's Journal* of 1917, on a rational method of using tuberculin. Your correspondent will there see the reasons for the reactions which he obtained.

Experiments show that in about 95 per cent. of animals tested with tuberculin a positive reaction indicates the presence of living germs in the animal's body. Though x-ray examination may have failed to disclose any evidence of pulmonary tuberculosis in your correspondent's case, yet the reaction he obtained proves conclusively that he is harbouring living tubercle bacilli.—I am, etc.,

Nordrach-upon-Mendip, Oct. 2nd.

GORDON TIPPETT.

Minor Medical Problems

SIR,—I am venturing to write to you about two small but interesting matters.

First, I wish to draw attention to the bad results I have had recently after the administration of potassium iodide. In one case, that of a male aged about 35, perhaps of rather a "neurotic" disposition, only 3 grains of potassium iodide were given, but within twelve hours his face had become swollen and his eyelids were oedematous. A friend of mine, a member of the medical profession, noticed that after taking 5 grains three times a day his neck and cervical glands were so swollen that he could not put on his collar. My former house-surgeon at Guy's Hospital reports two severe cases of nasal discharge and septic eruptions following upon the administration of small doses of potassium iodide.

Secondly, I wish to draw your readers' attention to the rather anomalous nature of the so-called "boil" during the last twelve months. In all the cases that I have seen or heard of recently apparently no definite slough occurred. In two cases a purulent discharge lasted a very long time—namely, eight weeks or so—without any core being formed or extruded. One of these cases terminated fatally from meningitis.

Doubtless the action of drugs and the reaction to disease may vary from time to time, but potassium iodide is a drug which is frequently given, and the formation of a boil is a common condition: it would be interesting and instructive to know of other medical men's experiences.—I am, etc.,

RALPH THOMPSON, Ch.M., F.R.C.S.

London, W., Oct. 8th.

"Port Sanitation and Common Sense"

SIR,—The letter of "M.D." (*Journal*, October 6th, p. 658) calls for a reply, for which I would crave your space and tolerance.

The main purpose of my article was to draw attention to the anachronistic nature of present-day port sanitation procedures, especially those of the Latin countries. I did not for a moment claim that any ship surgeon should be regarded as endowed with medical omniscience, only that he should not be treated, as happens in many foreign ports, as an ignoramus in respect of medical knowledge.

The cases which "M.D." mentions are admittedly difficult, and I for one would be only too pleased to have assistance in their diagnosis; but they are exceptional cases, quite different from the everyday minor illnesses which occur among human beings everywhere, ashore or afloat.

His assertion that infectious disease might break out on board during the twelve hours' transit of the Suez Canal is so very improbable as to verge on the fantastic. The health authorities of the Panama Canal zone are experts at their job, yet they require a declaration only at one end of that canal—the Atlantic for west-bound ships, the Pacific for east-bound. The case which he mentions of concealment of small-pox must in itself be anachronistic. I feel perfectly certain that no British ship surgeon (still in his senses) would nowadays attempt to conceal a case of small-pox, or even one that remotely suggested it. He would be only too glad to have it removed from the ship.

There certainly cannot be a multitude of forms, but there can be a variation in the attitude of the port doctor. He need not necessarily treat every ship surgeon as a medical ignoramus, and probably a liar in addition.—I am, etc.,

October 6th.

SHIP SURGEON.

The League and Peace

SIR,—Your annotation—"Cheese-paring at Geneva" (September 29th, p. 602)—cannot be read without arousing the deepest indignation at the indifference of the official mind to the common welfare. This indignation calls for expression; but how? Personal protest is useless, and political protest, because of the complexity of election programmes, is ineffective. There is, however, one course which should command the support of all. A way should be found for those who have the maintenance of peace at heart to unite to send an annual voluntary contribution directly to the League of Nations at Geneva. This would be additional to the sum of one penny and one farthing per head found with such difficulty by the British Government. Someone must take the initiative. Will the British Medical Association, as a professional body whose concern is our individual good health, therefore invite the representatives of other professional and also religious and social bodies to confer on the best means of making this proposal effective? In this you would have the earnest thanks of millions to whom one penny and one farthing is a tragically laughable price to pay annually for protection against war and for the encouragement of the arts of peace.—I am, etc.,

London, S.E.24, Oct. 2nd.

W. J. WISDOM.

The Services

NO. 14 STATIONARY HOSPITAL DINNER

The fifteenth annual dinner of the medical officers of No. 14 Stationary Hospital will be held on Friday, December 7th, at the Trocadero Restaurant, Piccadilly, at 7.15 for 7.45 p.m. Colonel C. R. Evans, D.S.O., will be in the chair. Price of dinner is 12s. 6d., exclusive of wines; evening dress or dinner jacket. The honorary secretaries are Colonel H. M. Perry and Dr. H. L. Tidy, 39, Devonshire Place, W.1.

DEATHS IN THE SERVICES

Surgeon Commander Archibald Denize Spalding, R.N. (ret.), died in London on September 10th. He was educated at the London Hospital, taking the M.R.C.S., L.R.C.P.Lond. in 1901, after which he entered the Navy, becoming surgeon commander on February 2nd, 1916. He served throughout the war of 1914-18.

Obituary

J. P. A. GABB, M.D.

Consulting Medical Officer, Royal Surrey County Hospital,
Guildford

Dr. J. P. A. Gabb, who died on September 18th, was the son of Dr. John Gabb of Bewdley, Worcestershire, and was educated privately at Clifton and later at University College, London, where he graduated, taking the M.B.Lond., with honours, in 1879 and the M.D., with honours, in 1882—the year in which he went to Guildford. He had also obtained the M.R.C.S.Eng. in 1879, and was awarded the gold medal for surgery and the silver medal for medicine. Dr. Gabb held the following appointments: honorary consulting medical officer to the Royal Surrey County Hospital; honorary medical referee to the Royal National Hospital for Consumption at Ventnor. He was president of the Surrey Medical Benevolent Society, and a Fellow of the Medical Society of London. He had been resident medical officer of St. Marylebone General Dispensary, house-surgeon at Kidderminster Infirmary, and house-surgeon and house-physician at University College Hospital. He was a member of the British Medical Association for fifty-two years.

H. B. B. writes: Dr. J. P. A. Gabb's death is an irreparable loss to his many friends; none of us now left in practice can remember a time when he was not there to be consulted in case of need—for he practised in Guildford for more than fifty years. He was a tower of strength to his junior colleagues—who consulted him freely—not only in purely medical matters, but in almost every concern in life that can affect medical men. His advice was always inspired by wisdom, often spiced with humour, and was given in such a friendly spirit that even when it was the reverse of that hoped for by aspiring youth it was comforting: hall-marked by reason. He was a shy man, very quiet and reserved, but his illuminating smile was celebrated. I have heard it said, rather enviously, that he owed his enormous practice to this smile, and I am open to believe that it contained healing properties, as an adjuvant to his vast experience and distinguished medical acumen and knowledge. His general practice was of the best kind, and included every class of society—and both rich and poor. All his patients were his friends, and they all loved him. There must be a very large number of people who will never regard any other doctor, however good, as "the doctor" in the same sense as they regarded Dr. Gabb. They could always rely upon him, and his mood was always the right mood. He was both generous and charitable. Dr. Gabb was a tall, handsome man, very strong, and in his prime, which lasted nearly to old age, he was untirable. He had little time for sport or recreation, but he loved his garden and his pigeons.

JOHN MACAULAY BOWIE, M.D.

F.R.C.S. Ed., M.R.C.P. Ed.

The death took place suddenly in Edinburgh on October 5th of Dr. J. M. Bowie, a well-known medical practitioner of the city. He was taken ill while driving his car, but was able to draw in to the side of the road; when he was carried into an adjoining office life was found to be extinct. Dr. Bowie, who was born in 1874, took a medical course at Edinburgh University, where he graduated M.B., Ch.B. in 1898, proceeding to the M.D. in 1901. In 1902 he joined the Royal College of Physicians of Edinburgh as a Member, and took the Fellowship of the Royal College of Surgeons, Edinburgh, in 1903. After a period as resident physician with the late Sir Byrom Bramwell in the Royal Infirmary, Edinburgh, he acted as house-physician

at Monsall Fever Hospital, Manchester, and as clinical assistant in the nose and throat department of the Royal Infirmary, Edinburgh. He later began practice in the Grange district of Edinburgh, where he enjoyed the confidence of his wide circle of patients to an unusual degree. In his student days Dr. Bowie took a keen interest in the Royal Medical Society of Edinburgh, of which he was honorary secretary, and he continued to devote himself to various professional organizations in later life. He was thus an active member of the British Medical Association; on several occasions he was a representative at the Annual Representative Meeting, and in 1930-2 was chairman of the Edinburgh Division of the Association. At the time of his death he was chairman of the Edinburgh Panel Committee, a member of the Scottish Committee of the British Medical Association and of the Edinburgh Insurance Committee, and chairman of the Clinical Club, a social organization for general practitioners in the city. He assisted in the organization of the Public Medical Service for Edinburgh which has just been started. During the war Dr. Bowie was medical officer to the 9th Royal Scots, and served with the rank of major in the R.A.M.C.(T.) in France, where he was severely wounded. For his services in France he received the Croix de Guerre. After his return he limited his practice to some extent, and removed to 10, Walker Street, Edinburgh.

Dr. Bowie is survived by a widow, two sons, and two daughters. Mrs. Bowie is well known for her activities in the nursing world, being connected with several nursing publications and an Associate of the Institute of Journalism. A memorial service held on October 8th at St. Cuthbert's Parish Church, Edinburgh, where Dr. Bowie was an elder, was attended by many representatives of the medical profession. The interment took place in the Dean Cemetery, Edinburgh.

D. L. FISHER, D.S.O., M.B., C.M.

Lieutenant-Colonel R.A.M.C.(T.)

Dr. David Leonard Fisher, who died on October 3rd at Darlington, was born on May 23rd, 1870, in Belfast, and studied medicine at Edinburgh University. He graduated M.B., C.M. in 1897, and after holding the post of demonstrator in anatomy for a time, was appointed house-surgeon to the Mildmay Hospital, Bethnal Green. He then practised in Stockton, and met his wife, a daughter of the late Mr. George Mellor, a member of the Stockton Council, and, accompanied by her, he went to Manchuria to take charge of a mission hospital until the Boxer rising. Returning home, he established himself in practice in the rapidly growing north end of Darlington, and afterwards in partnership with Dr. C. J. Kirk, taking part in all progressive work—first aid, St. John Ambulance, Territorial training, and later, service to the municipality of Darlington as a councillor in 1909, chairman of the Library Committee, and alderman in 1926, when he was elected chairman of the Health Committee. In 1921 he was appointed a justice of the peace.

Dr. Fisher had a most distinguished military career. Amidst a very busy practice he found scope for his illimitable energies in the Territorial Service in 1908, and at the outbreak of war was a captain of the 2nd Northumbrian Field Ambulance. Mobilized in August, 1914, he went to France in December with the 30th Division, having been in the meantime promoted major whilst stationed in camp at Gateshead. At the end of 1915 he was transferred to Salonika, where his brilliant self-devoting services and organization of field hospitals in the Struma and Vardar won him his lieutenant-colonelcy in 1916. He continued to serve midst all the trials of malaria, dysentery, and cholera in the East until his return to

civil life in 1919 with the rank of lieutenant-colonel. His war honours included mention in dispatches three times, the award of the D.S.O., and the decoration of an Officer of the Legion of Honour from the hands of the President of the French Republic.

In 1933, following the distressing event of the loss of two mayors in four months, Dr. Fisher was unanimously elected mayor of Darlington, and though still feeling the strain of those past years, so typical of his life, he manfully accepted the responsibility, and guided the council through a most difficult period in its history. He also held the appointment of police surgeon and medical referee to the War Pensions Committee. Always progressive, he was largely instrumental in forcing the pace in Darlington in the fight against tuberculosis in 1912, in the conversion scheme from privy middens to water carriage, in founding a museum, in replacement of noisy clanking tramways with trackless rubber-tyred buses, in modernizing water supplies, and finally in the co-ordination of medical services under the Local Government Act, 1929, when the whole of the council's activities were centralized under practically one roof, convenient to the new Memorial Hospital. Dr. Fisher joined the British Medical Association in 1903, and was chairman of the Darlington Division in 1925-6. He never made it his aim to amass money, but rather set himself to help his fellow man in whatever way he best could use his talents. His criticisms of colleagues were of the kindest nature. Always patient, always eager to believe the best, a true sportsman, he endeared himself to his friends and soon won over his opponents—if he ever had any.

A public memorial service was held at St. Cuthbert's Parish Church on October 6th, when a large congregation, consisting of the mayor, corporation, chief officials, and representatives of many organizations, paid their last tribute to a gallant soldier and a very faithful citizen. He leaves a widow and four daughters, two of whom are married, one to Dr. John Clarke (Coventry), and the other to Dr. James Robertson (Hull).

We have to announce with regret the death of Dr. G. A. F. HEYWORTH of Belper, one of the best-known medical practitioners in Derbyshire. During a hockey match, while playing for Belper against Beeston, he suddenly collapsed and died soon after admission to the Nottingham General Hospital. George Alexander Frederick Heyworth was born in 1881. From Rugby he went to Trinity College, Cambridge, and continued his medical studies at the London Hospital, obtaining the M.R.C.S. and L.R.C.P. diplomas in 1907, and subsequently the degrees of M.A., M.B., B.Ch. at Cambridge. While a student he played hockey for Cambridge University, and later for Lancashire. After a period as house-surgeon to the Children's Infirmary, Liverpool, he began general practice at Belper in 1909. He was a member of the British Medical Association (late chairman of the Derby Division) and of the Derby Medical Society, and among other interests he identified himself with the work of the local ambulance corps and of the Derby Branch of the Church Missionary Society. Dr. Heyworth's standing among his colleagues was shown by his election to both the Derbyshire Insurance Committee and the Derbyshire Panel Committee, and of the latter body he was at the time of his death vice-chairman and honorary secretary; he was also chairman of the Derbyshire Health Week Committee. Dr. H. W. Pooler writes: "A modest, charming, unassuming personality, Dr. Heyworth will be much missed by his colleagues on the Panel Committee. As one of the honorary secretaries of the joint ante-natal committee of the Derbyshire Branch Council of the British Medical Association and the Panel Committee, he was conducting negotiations with the Derbyshire County Council for the greater co-operation of general practitioners in ante-natal work throughout the county." A London consultant

writes: "As a friend and companion of some forty years' standing I would esteem it a privilege to be permitted to add a few words of tribute to the fine character of the late Dr. George Heyworth. We were cousins, and great good friends together at Rugby School, Cambridge University, and the London Hospital, and everywhere we shared rooms and worked in intimate contact. There was never anything in his good clean life which could not be admired—his loyalty to his friends, his devotion, his keenness and enthusiasm for all forms of manly sport, his sincere and Christian character, and his very fervid interest in the profession of his choice. George Heyworth died as he would have wished to die—in the full vigour of his fruitful life—but he had not yet reached the zenith of his power, and, had he lived, a still broader vista would have been open to him. The companions of his youth and of his prime are grateful for an example so inspiring as that of the friend who has been snatched away."

We much regret to record the death, on September 22nd, of Dr. JAMES CRAWFORD MYERS KINNEAR of Wickham, Hants, after an illness lasting several months. James Kinnear was born at St. Cyrus, Kincardineshire, in 1867; and after studying medicine at Aberdeen University, graduated M.B., C.M. in 1889. He practised in Scotland for a few years, and then, in 1900, came south to Wickham. He soon made friends, and rapidly found himself in extensive country practice. He held the appointments of medical officer and public vaccinator for Southwick and Wickham, surgeon to the Post Office, and honorary surgeon to the Shedfield Cottage Hospital. Dr. Kinnear was a good shot, a rider to hounds, and a breeder of horses. In his early days he was always in the saddle, doing his rounds on horseback. In this way, although often overworked and seldom taking a holiday, he managed to keep fit. He was devoted to his patients, especially the poor: they were his friends, their troubles were his, and his generosity to them was proverbial. It is not too much to say that, although a man of strong constitution, his devotion to duty and his unselfishness shortened his life. Dr. Kinnear's passing has left a gap in the district which will be difficult to fill, and he will long be remembered as a wise physician, a kind friend, a lover of the countryside, and a keen sportsman. He married in 1911 Mary Laura Duncan of Curdridge—a most devoted wife and mother—and leaves three sons and two daughters.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

On the occasion of the visit of the King and Queen to Cambridge on October 22nd, when His Majesty will declare the new University Library open, it is proposed to confer the honorary degree of Doctor of Science upon Lawrence Joseph Henderson, M.D., professor of biological chemistry at Harvard University, and upon Karl Landsteiner, M.D., member of the Rockefeller Institute for Medical Research. The Vice-Chancellor, Mr. J. F. Cameron, Master of Gonville and Caius College, in his address to the Senate on October 1st, made detailed reference to the new University Library, with the opening of which a new chapter in the history of Cambridge begins. He recalled the part played by his predecessor, Sir Hugh Anderson, M.D., in securing for the University the great gift by the Rockefeller Foundation, and said that the Anderson Room would commemorate Sir Hugh's services.

UNIVERSITY OF LONDON

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

The following candidates have been approved at the examination indicated:

ACADEMIC DIPLOMA IN PUBLIC HEALTH.—Hyacinth I. Lightbourne, F. G. Macdonald, I. A. MacDougall, I. I. Roberts.

LONDON HOSPITAL MEDICAL COLLEGE

The Second Open Entrance Scholarship of the value of £100 has been awarded to E. A. Pask (Downing College, Cambridge.)

UNIVERSITY COLLEGE HOSPITAL

Three lectures on the history of medicine will be delivered at University College Hospital Medical School, University Street, W.C., on Mondays, October 15th, 22nd, and 29th, at 4.15 p.m., by Professor Charles Singer. The first lecture will be on Hippocrates, the second on Galen, and the last on Boerhaave. The lectures are open to all medical students of the University.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

DIPLOMA IN PUBLIC HEALTH.—H. V. M. Jones, J. H. St. B. Crosby.

Medico-Legal

DEATH AFTER "CANCER CURE"

Inquest Jury's Rider

The Westminster coroner, Mr. Ingleby Oddie, sitting with a jury, concluded an inquest on October 1st on the body of Alice Bishop, aged 62, a Streatham woman, who died after having been under treatment for four and a half months in a home run by Mr. David Rees Evans of Finchley Road, Hampstead, a herbalist, who professed to have discovered a cure for cancer, the nature of which, however, he had not made public. It was stated that Miss Bishop had remained in the home until September 15th, when, on the advice of a qualified doctor, she was removed to a nursing home, where she died six days later, the cause of death being syncope following toxic absorption due to ulcerated carcinoma, an inoperable growth.

Evidence was given by a woman friend of the deceased as to the condition of the room in Evans's house in which Miss Bishop was a patient. She did not think it was all it might have been, and she did not consider it sufficient to change the bedclothes once a fortnight. A Hampstead medical man stated that he was called in in May to see Miss Bishop at the home of Evans, whom he did not know personally. She told him that she had been suffering from hiccup and pain, and he treated her, but she had suggested that she did not want any treatment for her cancer (of the breast) other than that given by Mr. Evans. The practitioner told her, after one or two visits, that he could not continue to see her in the house of an unqualified man.

Mr. Evans, who was cautioned by the coroner before giving evidence, said that he was 41 years of age, and a "healer of cancer." He had no medical training or knowledge of pathology. He had had four patient-boarders in his home at the same time; his charges were from two to three guineas a week for board and from two to six guineas a week for treatment. He had charged Miss Bishop seven guineas altogether. He met her first in April at a meeting where he lectured on cancer, and where six of his cured patients were present. He examined the growth on her breast, and concluded that it was an advanced case of cancer. She came to him every day for three weeks, and he painted a herbal preparation over the diseased area with a small brush. The object of the paint was to draw the cancerous growth to the surface, it was not a caustic or acid, but he refused to divulge its composition. Miss Bishop had shown some sign of improvement at first, but later lost the will to live. Mr. Evans was questioned concerning an action brought against him by a Mrs. Burrell in 1930, but he denied that the liquid on that occasion was analysed and found to be Venice turpentine.

After two women had given evidence on Mr. Evans's behalf, one of them stating that she had been cured by him of cancer of the breast, the coroner, in summing up, said that it was well that such persons as Mr. Rees Evans should know the risks they were running. Mr. Evans was completely ignorant of medicine and surgery, yet he held himself out as able to cure a disease which had baffled the whole world. If he had such a secret remedy, ought he not to hand it over to the numerous sufferers from this terrible disease? He did not do so; he kept it to himself. The result was to buoy up false hopes, and to intervene between the patients and surgical or deep-ray treatment, which were doing so much in these days.

The jury at first returned a verdict of manslaughter, but the coroner pointed out that for such a verdict to stand it would have to be proved that the treatment had either caused or accelerated death. The foreman replied that eight of the jury had said "manslaughter" and one "gross negligence." They had considered the evidence and the pain the deceased had suffered. The coroner said that pain did not necessarily shorten life. After further consultation the jury returned a verdict that death was due to cancer—that is, natural causes—accelerated by lack of treatment, and in a rider they condemned the interference and negligence of Rees Evans's treatment.

* * The case of Burrell v. Evans, to which reference was made in the above proceedings, was heard before Mr. Justice Charles and a jury in 1930. The jury were unable to agree on an answer to the question put to them as to whether there had been fraudulent misrepresentations and negligence by the defendant. The case was fully reported in the *British Medical Journal* (1930, i, 1024).

Medical News

The President (Dr. J. S. Fairbairn) and Council of the British College of Obstetricians and Gynaecologists have issued invitations to a dinner party to be held at Claridges' on Monday, November 5th.

A meeting of the Royal Microscopical Society will be held at B.M.A. House, Tavistock Square, W.C., on Wednesday, October 17th, at 5.30 p.m., when papers will be read by Dr. Edwin E. Jelley and Drs. G. M. Findlay and R. D. Mackenzie.

The annual dinner of the Chelsea Clinical Society will be held at Hotel Rembrandt, Thurloe Place, S.W., on Tuesday, October 16th, at 8 o'clock. The president will receive members and guests at 7.30 p.m.

The annual dinner of the Surgical Instrument Manufacturers' Association will be held at the Holborn Restaurant on Friday, October 26th, when the principal guest will be Dr. William H. Ogilvie.

The first part of a course of lectures to be given at the British Red Cross Society's Clinic for Rheumatism, Peto Place, Marylebone Road, N.W., commences on October 18th, and will be continued on alternate Thursdays at 8.30 p.m. to December 13th. The second part of the course will open on January 3rd, 1935, and will be continued on alternate Thursdays at 8.30 p.m. until April 4th (with the exception of February 14th). All inquiries regarding the lectures should be addressed to Dr. M. B. Ray at the Clinic.

A course of three public lectures will be given by Professor L. J. Henderson of Harvard University at University College, Gower Street, W.C., on October 16th, 17th, and 18th at 5 p.m. Professor Henderson's first lecture will be on "Physiological Equilibrium," and Professor A. V. Hill, F.R.S., will occupy the chair.

The British Institute of Philosophy (University Hall, 14, Gordon Square, W.C.) has arranged a course of four lectures on the importance of a philosophy of life for mental health, for the medical profession, on Thursdays at 5 p.m. from November 1st to 22nd. The first lecture, on "The Biology of Social Life," will be delivered by Professor W. Langdon Brown; the second by Dr. William Brown on "Health, Self-determination, and Free Will"; the third, on "Creative Activity and Mental Health," by Dr. Emanuel Miller; and the fourth by Dr. H. Crichton-Miller on "Belief and Adaptation." Applications to attend the course, the fee for which is 12s. 6d., should be made to the director of studies at the Institute.

Free demonstrations of the technique of contraceptive methods will be given at 108, Whitfield Street, W.1, on November 1st and December 6th, 1934, January 3rd, February 7th, March 7th, April 4th, May 2nd, and June 6th, 1935, from 2.30 to 6 p.m. Previous applications for tickets (which will be supplied to medical practitioners only) should be made in writing to the honorary secretary, C.B.C., at that address.

Dr. R. Veitch Clark, medical officer of health for Manchester, will deliver his presidential address to the annual meeting of the Society of Medical Officers of Health on Friday, October 19th, at 5 p.m., at 1, Upper Montague Street, W.C.

The South-West London Medical Society announces a new series of lectures beginning on October 17th, when Dr Russell J. Reynolds will speak on cineradiography. All medical men are welcome at this meeting. Other lectures will be given as follows: November 14th, Dr. L. J. Witts: "Diagnosis and Treatment of Anaemia." December 12th, Discussion on anaesthesia, "Ether is not Dead," to be opened by Dr. Z. Mennell and Dr. M. D. Nosworthy. January 9th, 1935, Mr. B. Whitchurch Howell: "Orthopaedic Cases in General Practice." February 13th, Dr. Donald Paterson: "So-called Acidosis Attacks." April 10th, Dr. G. E. S. Ward: "The Failing Heart." May 8th, Mr. Terence Millin: "The Obstructing Prostate." The session will conclude with the Bolingbroke Lecture, on June 12th, by Dr. Robert Hutchison, entitled "Constitutional Medicine." Meetings are held at the Bolingbroke Hospital, Wandsworth Common, S.W.

The fifth centenary of the foundation of the University of Catania will be celebrated from October 19th to 22nd.

A series of post-graduate lectures will be given at Ancoats Hospital, Manchester, on Thursdays at 4.15 p.m. from October 18th to December 13th inclusive.

The Fellowship of Medicine, 1, Wimpole Street, W.1, announces that lecture-demonstrations will be given at 11, Chandos Street, W., at 2.30 p.m. on October 16th and 23rd. Courses of instruction include week-end courses in clinical surgery at the Royal Albert Dock Hospital on October 20th and 21st; and in diseases of the chest at the Brompton Hospital, on October 27th and 28th; a fortnight's course in gynaecology at the Chelsea Hospital, October 22nd to November 3rd; a week's course in neurology at the West End Hospital for Nervous Diseases, October 29th to November 3rd. Cases will be demonstrated at the National Temperance Hospital, Hampstead Road, at 3 p.m. to-day (Saturday), October 13th. A course of lectures on diet and dietetics will take place on Wednesdays at 8.30 p.m. at 11, Chandos Street, W., from October 24th to December 12th. The first will deal with general principles of dietetics, and will be followed by diet of infants, of the diabetic, of the obese and thin, for convalescents and aged, in deficiency diseases, in the nephritic, and in gastric diseases. Courses and clinics are open only to members and associates of the Fellowship.

At a meeting of the Académie des Sciences in Paris on October 2nd, Dr. Nicolle, director of the Pasteur Institute of Tunis, gave an account of recent investigations by his collaborator, Dr. Joan Laigret, into the mechanism of immunization against yellow fever. In the course of three months more than 3,000 persons have been inoculated against yellow fever in French West Africa, and the results have been so satisfactory that the authorities have decided to make vaccination against yellow fever compulsory.

The Hanbury memorial gold medal of the Pharmaceutical Society of Great Britain has been awarded to Dr. George Barger, F.R.S., professor of chemistry in relation to medicine in the University of Edinburgh. This medal is for "high excellence in the prosecution or promotion of original research in chemistry and the natural history of drugs."

The second Italian Congress of Industrial Medicine will be held at Turin from October 20th to 23rd.

A new apparatus for the treatment of cancer by high-voltage x-rays has been given to the Birmingham General Hospital by Sir Herbert Austin, who has also provided the building which houses it, at a total cost of £4,000.

The issue of *Paris Médical* for September 22nd is devoted to psychiatry.

Professor P. Nobécourt has been elected president of the Société de Pédiatrie de Paris.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology

Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscra Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Barillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumsheugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Localized Flushing

"H. H. B." writes from Lancashire: I should be much obliged if any of your readers could offer suggestions as to appropriate treatment in the following case. A young unmarried woman, aged about 20, suffers from patchy circumscribed areas of flushing on very slight provocation, chiefly on the face, neck, and upper chest. Her general health is good, her only complaint being a certain degree of simple anaemia, which responds readily to treatment with iron preparations. She is not a particularly nervous type either. I presume that the cause must be some disturbance of the vasomotor mechanism.

Treatment of Erythema Annulare

"S.Q.S." writes: I shall be most grateful for advice regarding a patient who gets frequent recurrent attacks of erythema annulare. The rings vary in size; they only come on the outside of the thigh (right); irritation is great, and treatment—external and internal—is a failure. A friend suggested to the lady to use a cloth soaked in hot water to slap the part. This she does, and it is the only application that gives temporary relief from the terrible itching. Calamine lotion with carbolic acid does help a little at times, but the rings return. A sister has had chilblains which nobody can cure. Another sister gets erythema nodosum, which has baffled doctors galore.

Diuresis in Case of Pituitary Tumour

Dr. T. MacCARTHY (Sherborne, Dorset) would like to know if an explanation can be given as to the source of the fluid excreted by a case of pituitary tumour in which the patient over a period of four months has passed an average of 240 ounces daily, her average intake not having been more than 80 ounces from all sources, and often less than 60 ounces daily. Meanwhile she has lost no weight. It appears to be a mystery where the fluid comes from. Does she absorb it from the air? I can think of no other answer. She is not very thirsty, and shows no signs of dehydration.

Income Tax

Retirement from Foreign Practice

"R. S." is carrying on a practice abroad, and proposes to sell it as from April, 1935, and return permanently to this country. His income then will consist of (1) dividends on investments, (2) war disability pension, and (3) probably proceeds of locumtenent work. On what basis will he be assessed?

(1) In so far as they are not taxed by deduction, on the basis of the yield of the investments in the previous year—or the current year for 1934-5. (2) No liability to tax. (3) On the current year's earnings, except that if

"R. S." does that sort of work for two or three years he will probably be assessed on the previous year's basis, except for the first year.

Compensation for Loss of Office

"HOPEFUL" is in receipt of compensation for loss of office paid quarterly. Is it liable for payment of income tax, and, if so, is it regarded as earned?

* A lump sum by way of compensation would not be liable to tax, even if by arrangement paid in instalments. But the sums received in this case are apparently quarterly payments for an indefinite period, and would seem to be more in the nature of a pension. In that case they are liable as earned income.

LETTERS, NOTES, ETC.

A Case of Erythroedema

Dr. J. A. MOORE HALL (Shotts, Lanarkshire) writes: I was recently called to see a female child, aged 13 months. For several weeks the mother noticed that the little patient was becoming very restless and irritable. Naturally, she attributed the condition to dentition. However, when the greater part of the night's rest was broken by the crying of the baby, she thought it time to consult the doctor. On examination the patient's hands and left foot were found to be swollen and red and cold to the touch. This was accompanied by profuse perspiration and marked photophobia. There was loss of appetite and weight, together with constipation. The pulse was accelerated, but the temperature was found to be, and remained, subnormal. The urine was free from albumin. There was no evidence of rickets. A day or two later a very irritable sweat rash appeared on the neck and body, but this condition was soon relieved by the application of a lead and tar lotion. With rest in a shaded room and sedative treatment, the above signs have improved, but there are still marked general asthenia and muscular hypotonia. In my opinion, the child is suffering from erythroedema, which is also known as pink disease on account of the curious pink or red colour of the hands and feet. I am led to write this communication regarding an uncommon disease found in general practice, as I feel sure that many of my fellow-practitioners have met with cases similar to the above, which have proved puzzling. The main signs of the fully developed condition have been aptly described by A. Victor Neale in an alliteration of the words beginning with "P": peevishness, pinkness, pallor, perspiration, papules, peeling, pulse, posture, photophobia, paraesthesia, paresis, pyuria. The disease usually attacks children from 3 months to 5 years of age, even those who are well nourished, and lasts from three to nine months. The cause of the condition is unknown, and there is no specific treatment. A peripheral neuritis mainly affecting the sensory nerves, and showing a secondary vasomotor disturbance of the extremities is the principal pathological finding. Violet-ray treatment and raw liver (1 to 2 oz. daily) are said to have a beneficial effect. Fresh air, warmth, subdued light, rest, wholesome food, together with a lotion for the troublesome rash, are essential. Convalescence is usually slow, but the prognosis is good.

The Swab in Diphtheria Diagnosis

Dr. JANET M. C. GRAY (Lewisham) writes: I have read with much interest the letters on diphtheria in the *Journal* of September 22nd and 29th. Most of the time I have been working in India, but was home on furlough in 1915, and for a short time was doing general practice. I had a fair number of cases of diphtheria in children: in each case, after taking a swab, I injected a full dose of the antitoxin, and all the cases recovered. As I never got an answer about the swab until the next day—it was a place in the country—I think the results might have been different had I waited. In India diphtheria is very rare, and, although I never had a case, I always kept antitoxin by me, because I felt so strongly there was no time to be lost.

Evipan Anaesthesia

Dr. J. T. SPIRIDION (Hankow) writes: I would like to add my own very satisfactory experiences with sodium evipan to those of Dr. Burke, published in the *Journal* of August 11th (p. 255). During the past three months I have used this anaesthetic on ten patients only—nine Europeans and one Chinese. It was given for the following minor operations: tooth extractions, four; opening deep abscesses, two; curettage, one; setting a fractured femur, one; repair of

perineum, one; repair of crushed toe, one. No premedication was given in any of the cases: in one only was the operation performed by myself. All the patients enjoyed good general health, although two were alcoholic subjects; one of these required 11 c.cm. before losing consciousness—an unusually large dose—and the other suffered from a severe rigor one hour after the operation. In all the other cases the anaesthetic proved perfectly satisfactory and pleasant for both surgeon and patient. The theatre temperatures during the operations varied from 85° to 99° F., the average temperature being 92.4°. Sodium evipan does not, therefore, appear to exert any harmful effect on the liver during its detoxication, although the liver functions are easily upset in such hot weather. I believe the drug to be a very suitable anaesthetic in tropical areas where nitrous oxide is unobtainable.

Bacteriological Warfare

"M.D." writes from Yorkshire: We have read many articles recently in the popular press about destroying vast populations by bacteria spread from aeroplanes so cunningly that they can even find their way down the moving stairs into the tube stations. How horrible! Unfortunately I am not a bacteriologist, and so I appeal for information as to what variety of coccus or bacillus might be the innocent agent of such a campaign. I could conceive of masses of bacilli of the typhoid group being thrown down on water supplies, but it would be easy to combat this by boiling our drinking water. Again, would showers of *B. pestis* produce plague in the towns powdered with them, as a flea is usually the agent which carries it, so that it would be necessary to breed huge quantities of infected fleas and broadcast these in order to affect the underlying population to any appreciable extent. Even throwing down influenza germs would probably cause more stir among the bacteriologists, who would be arguing about their exact nature, than among those contaminated. But seriously, it appears to an ordinary physician that many alarmist declarations have been made in the Press for which there is inadequate basis; or are there bacteria which are so infectious that masses of people who come in contact with them, as they would were the germs spread from aeroplanes?

Gonococcal Infection

Dr. R. V. STORER (London, W.1) writes with reference to the notice of his book *Gonococcal Infection: Recent Advances in Pathology, Diagnosis, and Treatment*, which appeared in our issue of September 29th (p. 595). My views on this disease may seem "frankly heretical" to your critic, according to his own standards, but they have been accepted by venereologists in this country and America as being "sound and rational." Mr. Kenneth Walker, in his foreword, pointed out that this book "was marked by originality of thought and freedom from conventional views," but also suggested that "the fact that some of the author's dicta will meet with opposition is surely no disadvantage." When a medical man presents the results of his private research and clinical experience to his fellow practitioners, especially if his methods depend on a new concept of the pathology of a disease, I suppose he must expect to be called a "heretic," even though he is able to report a maximum degree of success. Your reviewer complains that the book contains "far too many errors," yet he mentions a trivial one only—namely, a figure based on a simple mental calculation, the mistake in which would be obvious even to a schoolboy. It has not been my desire to pose as a pontiff, as your critic suggests, but to present in all humility, and with due appreciation of its shortcomings, a clear, concise account of recent advances in gonococcal infection, based not only on the published works of other authorities, but on an experience gained by the intensive personal study of over five hundred cases throughout their course.

On October 15th the Edinburgh Branch of Watson and Sons (Electro-Medical) Limited, is moving to more commodious premises at 86, George Street, where there will be improved facilities for service work, and a showroom for the demonstration of apparatus.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 49, 50, 51, 54, 55, and 56 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 204.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, OCTOBER 20th, 1934

The Harveian Oration

ON

"INVENTIONS AND THE OUTLOOK IN NEUROLOGY"

DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS OF LONDON
ON OCTOBER 18TH, 1934

BY

JAMES COLLIER, M.D., F.R.C.P.

CONSULTING PHYSICIAN AND EMERITUS LECTURER IN NEUROLOGY, ST. GEORGE'S HOSPITAL;
PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE

For us, his posterity, Harvey is the first to pick up the threads of experiment and observation begun by Galen in the correct deductions from his lesions of the spinal cord in frogs and rabbits, continued by Aristotle, and thereafter broken for 1,500 years, and he is styled the "Father of modern physiology." From the manner of his work in experiment and in observation of proofs he is the inventor of modern methods of research. From the law which he laid down of "Omne vivum ex ovo" he is the starting-point in the idea of evolution. From his inspired flight of thought expressed in the words "Epidemic, contagious, and pestilential diseases scatter their seeds and are propagated to a distance through the air and in hidden fashion silently multiply themselves by a kind of generation" he is the prophet of bacteriology to come. He is the discoverer of the circulation of the blood. To his colleagues and to his patients he was the "beloved physician," and in this College he receives homage upon each St. Luke's Day as its most illustrious fellow.

Harvey's exhortation to us is "To search out and discover the secrets of Nature by experiment and observation." The first experiment is in a flight of thought; a wandering of the mind which begets a sudden new idea, a flinging away for the moment of all we have taken on trust as gospel, or sometimes an attempt to explain in words to others what we ourselves do not understand, has brought discovery. No one ever made successful experiment but he had already conceived that something would happen from it, nor an invention without the idea as to how it would work. However much Harvey may have denounced mere speculation in others, yet guided by his careful observation it was his primary method of work. He had, surely, a firm conviction that the blood did circulate, and in a certain way before he put his experiment into being. He had surely conceived that the "to and fro," "ebb and flow" movements of the blood, which had been gospel since the time of Galen, could not be, and was driven by dissatisfaction to make his great discovery.

There is no method in discovery; sometimes there appears to be a high element of fortunate chance. Great knowledge is not always essential; at times it seems a hindrance to personal progress, for much of a very wide knowledge is of necessity taken on trust without even reasonable personal analysis. A castle builded in the air by a highly knowledgeable fancy in the course of a week-

end of leisure, and a lifelong plodding with microscope and stains, have both on occasion brought an equal advance in medicine, though the labour entailed in the two events is so unjustly different. It is remarkable that in former times, when knowledge of medicine was scant, the pioneers, in expressing their brief views upon physiology and disease, and particularly in teaching their pupils, gave explanations that would sum up in a nutshell our accepted knowledge of the present day after a century of discovery and proof. Such flights of thought, such lucky hits upon the real truth are, I submit, dismissed by posterity as dreams without discovery and without appreciation of their greatness. They are in reality potential discoveries not followed up, probably from lack of continuing interest, certainly from the lack of methods and of knowledge as to how to find proofs. In attempting to hold your interest upon inventions and their effect on the progress and present outlook in neurology, I shall draw your attention to several prophetic flights of thought, all of which were great, and some of which resulted in important advances in knowledge.

I have chosen the word "invention" as best fitting the bringing in of a new idea—an invention of the mind, which may prove to be a discovery of the truth or may fail as a false hypothesis—as well as the bringing in of a demonstrable fact or of a new method. Wonderful inventions for the study of the structure of the nervous system and tireless research have resulted in knowledge, practically complete, of the most intricate and marvellously beautiful network, with input paths leading from the outside world and output paths leading to the muscles for action, almost incredible in its extent, everywhere continuous, and so complicated that it is impossible to prove or to conceive how it works except in a few of its lower and grossly mechanical regions. This vast and solid edifice of proved knowledge of structure has added little to our knowledge of function and disease. But it is a very important little, for it is all we have, and it is concerned with the lower and more grossly mechanical regions of the spinal cord and brain stem. This quarry has been worked out, and labour in it has well-nigh ceased. Delving into the function of the nervous system by experiment has reached so high a refinement that the signals by which each part works can be made visible and audible. Always the same signals in every part alike, only more and more rapidly repeated as the message becomes stronger and more urgent, and the end-result of these fine labours is

some knowledge as to how the lower and simpler regions—namely, the spinal cord and the brain stem—work. To the greatest of living physiologists who has spent a long life in the experimental study of the nervous system, the Rede lecturer for last year, Sir Charles Sherrington, the highest and largest part of the nervous system, the brain, is still mainly a form and a series of events, and his ignorance of much of their relation bids him despair. Yet proclaiming himself an optimist, as opposed to a defeatist, he puts the question: "Will it ever be possible to understand the nervous system?"

In the recognition and distinction of the nervous diseases the past century has brought an ever-increasing and now almost complete knowledge, which does not yet, and will not, reach finality, for disease is subject to evolution and devolution and disappearance at least for a time. The causation of many of the diseases is now clear, and in recent years studies of biochemistry and virus infection have brought suggestions of what the future may discover in maladies of which we do not know the cause. Methods of treatment, though far behind those of diagnosis, are advancing, and at the moment we seem to be in possession of means of diagnosis and treatment which will surely remove the terrible diseases general paralysis and locomotor ataxia from the community. Yet the fact remains that the four most prevalent and relentless of the nervous diseases—disseminated sclerosis, progressive muscular atrophy, paralysis agitans, and most of the vascular diseases—come before us without any clue as to their cause, and without any means whatsoever of their prevention, nor even, as in the case of progressive muscular atrophy, of the slightest amelioration.

Cerebral Localization of Function

The means by which invention begins, the arousing of that lasting interest which does not rest until discovery is made, is often intangible and a thing per chance and of personality, but sometimes it has been recorded, and I may introduce the great discoveries in neurology with an instance. At the end of the eighteenth century a self-conscious lad pondered upon his disability promptly to answer in class the things he knew well, and concluded that it was because nature had not given him a fine forehead and prominent eyes. His interest in the brain and speech never thereafter left him. He became a very great anatomist of the nervous system, and he proved, by his dissection, the definite structural path from brain to muscle partly crossing in the medulla—the pyramidal path—and his proof was then and there accepted by the knowledgeable world for all time. Like Harvey, he was not the first to perceive this, but, like Harvey, he gave such proof of its truth that no one wished to deny it.

Gall's discovery of a definite pathway conveying movement from brain to muscle was the foundation of all subsequent work on the paths of function within the nervous system. In his early days he laid down the truest conception of the brain as the exclusive seat of the highest nervous functions only. By his conception of speech as a function of the forward part of the brain he was the originator of the idea of localization of function in the brain. It does not detract from the greatness of the discoveries of this remarkable man that he went over to phrenology and died discredited, torn from his high position by the prophetic denunciation of Flourens that there are no separate highest functions to be localized in the brain, but that all are interwoven. Round Gall's conception of cerebral localization such a war was waged during the nineteenth century—complete defeat at first, then, after years, complete triumph, and later, defeat not yet complete—as has stimulated more investigation and produced more useful discovery than any other event in

the history of neurology. At the moment the localization of function in the brain is presumed by our physiologists, but admittedly without means of scientific proof. The only proved localization of function is that of the conduction tracts—the input and output paths which connect the animal with the outside world.

Invention of Histological Technique

In 1835 Purkinje, an Austrian priest of gipsy family, became possessed of a microscope. In a short space of time he had discovered the nerve cell, and this discovery, added to that of Gall of the nerve tract, was the instigation of all later work. He had invented a hardening reagent, bichromate of potash, which would allow sections of soft tissue to be cut; a machine, the microtome, to cut the sections; a stain, carmine, which would bring out the details; a clarifying reagent, oil of cloves, which would make microscopical examination possible; and a method of making permanent preparations with Canada balsam. Purkinje's work was epoch-making in the progress it caused. As the fruits came at once the establishment of the cellular theory of tissues from Schleiden and Schwann, and the cellular pathology of Virchow. Rosenthal demonstrated that the nerve tract was made up of fibres springing from the nerve cell, and Schwann found the insulating sheath which protects the nerve fibres. Waller, by his methods of degeneration, commenced the tracing of the nerve tracts within the nervous system.

Thereafter, with the wonderful discoveries and patient work largely of the German School, in which the names of Weigert, Etinger, Cajal, and Golgi are prominent, the structure of the nervous system has been made known with such delicacy of detail, such intricacy of connexions, such enormity in amount, as to be altogether outside the possibilities of present-day comprehension of the relation of structure to function except in its lowest and least complicated regions. It is referred to nowadays as one entity, "the nervous network," just as it was first named the "sensorium commune" a century and a half ago.

Discovery of Reflex Action

In 1784 a professor of anatomy in Moravia wrote a very short account of the nervous system, and in attempting to explain how it worked said that "physical and mental stimuli acting upon ascending nerves are conveyed directly through the ganglia and network of nerve threads, to be reflected thence by means of descending nerves with a result in action." This wonderful discovery in thought of reflex action, arrived at so far as we know without definite experiment, is the foundation of most of what we now know concerning the way in which the nervous system works. I will ask you to compare these words of Prochaska with those of Sir Charles Sherrington in the Rede Lecture for last year: "Brain and nerve are but a skillfully laid train of powder between the muscles it fires and the restless world outside which fires it. The question, who pulls the trigger, is easily answered. It is the outside world." And again: "An animal's motor behaviour where the brain nets are large excels in variety and nicety, but it fails to offer anything radically different from reflex action elsewhere." By actual experiment Sir Charles Bell at the Middlesex Hospital, Magendie in Paris, and others discovered the function of the spinal roots as input and output paths by which reflex action is carried on, and Bell most importantly first conceived of the long reflex processes which went as high as the brain. Now all unconscious action is reflex action. The great Pavlov and others have shown us how large a part reflex action plays in conscious action and behaviour.

It is when we arrive at those processes in the brain which are not traceable to outside stimuli and cannot be reduced to the principle of reflex action that our knowledge of the working of the mechanism fails rapidly and finally. I may perhaps give you a simple example of the utter dependence of high cerebral function upon a reflex process. When I speak to you my speech does not flow out from well-trained speech centres in the brain as does water from a full cistern. I must have an immediate and delicate reflex return reaching me by my ears and by the sensation of movement of my lips, which keep me instantly informed as I go along that what I am saying is in correct pattern. If anything blocks the path of both those reflex actions I shall not be able to finish even a sentence, my speech, though long practised, will break down at once into an inarticulate jargon in which both words and pattern disappear. If through a faulty attention to my reflex signals I miss out an important word, my meaning tends to become unintelligible to my listeners and my speech an imperfect function.

The Hypothesis of Nervous Function

Hughlings Jackson, who is the pride of English neurology as Harvey is of English medicine, greatly influenced and moulded the present position of neurology. In method he was the ablest deducer from what seemed to be the minimum of observation, but his chief genius was that he was a relentless dreamer, who criticized with a positive inquisition all his flights of thought, and apparently only gave to the world those which survived this ordeal, for there is hardly a thing of his which has not borne the test of time. He conceived that Nature had builded the nervous system upon the same pattern of function in its several parts: that, at the lower stations, the local requirements of the individual segments of the body were looked after, but that, at higher levels, the requirements of everything below were subserved in increasingly compound proportion; and that, at the highest levels, the nervous system was concerned with the requirements of the animal as a whole—perhaps some of these concern some parts of the brain more than others.

This remarkable conception, which arose when popular belief was convinced that centres for separate functions in the several parts of the brain were ascertained facts, is substantially the proved knowledge of the present day. The supporters of the belief in local centres of function in the brain had forgotten their parent Gall, and the simple but emphatic statement by which he was overthrown: "There are no such separate functions for localization." I may perhaps put it like this: the functions of seeing, hearing, and feeling are clearly separate so far as the nerve terminations in the eye, ear, and skin are concerned, but when a stimulus from one of these organs reaches the nervous network it becomes modified by all the other stimuli which are in-coming at the moment, and the higher in the nervous system it spreads this modification increases, so that it becomes more and more difficult to think or to speak of it as a stimulus in one isolated function such as vision, hearing, or feeling. Hughlings Jackson wrote: "I cannot conceive any function of vision apart from the function of movement."

It seems clear that the local loss of function which one sees daily from lesions of the brain is the result of the blocking of the input and output paths, and I have arrived at the conclusion that when mental defect occurs from a not too extensive local lesion of the brain it results from a block upon those important tracts which put the several regions of the brain in touch with one another, and never from lesions of the higher regions of the brain, which were formerly supposed to subserve mental functions exclusively. Therefore we have now the

vast expansion of the brain, in the words of Sherrington, "as an input and output signalling system which is newly arisen as a gigantic combining mechanism for the signals from the outside world and as a dominant part of the nervous system which tends to deal with the requirement of the animal as a whole more than does any other part."

Locomotor Ataxy and Peripheral Neuritis

One of the most remarkable discoveries in the flight of thought, and one which became a proved principle a century later, came from the distinguished founder of King's College Hospital, Robert Bentley Todd, in an attempt to explain lead paralysis to his pupils. He said: "I believe that the muscles and nerves are early affected, and that at a later period the nerves centres may become implicated. The nervous system is thus first affected at its periphery in the muscles and nerves, and the poisonous influence, continuing the contamination, gradually advances towards the centre." Recently it has been shown by Aub and others that in lead paralysis accumulation of the lead occurs first in the affected muscles, and that the poison seeps up through the nerve endings into the nerves, and reaches the central nervous system. It is now generally accepted that the nerves are protected by their fatty sheaths against the advent of poisons and infections everywhere save where the nerve endings are exposed in the extreme periphery, and that it is only in these exposed terminals that noxious agents can gain access, and that they travel by a process of seepage along the nerve filament to gain the central nervous system. Viruses that affect the nervous tissues travel in the same way, and seemingly spread universally. As the only nerve terminals exposed to the outside world are the olfactory terminals in the nose, it follows that virus infections of the nervous system must be acquired by droplet infection of the nose or by wounds which expose the nerve filaments to infection.

Dr. Todd, who was by far the greatest clinical neurologist Britain had produced until the time of Hughlings Jackson, was the first to begin the breaking up of the spinal diseases, at that time all classed as "paraplegia," by his discovery of locomotor ataxy as a distinct clinical entity. He did this with his usual vivid imagination and his customary absolute faith in his own powers of clinical and post-mortem observation. He stated that the antero-lateral region of the cord was the path for common sensibility, and that the cerebellum was the organ commanding position and posture, and that the posterior columns were subservient to the cerebellum in conducting to it peripheral impressions of position for its guidance, and he made the separation for the first time between spinal paraplegia and spinal ataxy. Todd wrote this four years before Romberg wrote his work, eight years before Russell Reynolds described the disease as "muscular anaesthesia," and eleven years before Duchenne christened it "progressive locomotor ataxy."

Lumbar Puncture

In the year 1891, and in a quiet way, came an experiment which slowly led to the most astounding progress in our knowledge of nervous disease and of its diagnosis, differentiation, and treatment. No event in the history of neurology has brought so many assets as has the introduction of lumbar puncture. Quincke of Magdeburg conceived that he might relieve the symptoms of hydrocephalus by draining the cerebro-spinal fluid. Six years previously Corning in America had drained the fluid for the treatment of tuberculous meningitis, but Quincke was the first to make his work known throughout the world. The discovery of changes indicative or characteristic of certain diseases in this hitherto unimportant

fluid soon followed, and lumbar puncture has become a routine in diagnosis and treatment.

It has given us the means of speedy relief from the agonizing pain and danger of increased intracranial pressure, the cure of epidemic meningitis, of cerebral uraemia, of bromide and barbitone poisoning, and it has given us spinal anaesthesia. It has led to the discovery of the clinical features of meningeal haemorrhage and its common cause in leaking aneurysms, to the easy recognition of the many forms of meningitis, and gives definite indications of prognosis in the sugar, chloride, and cell content. Pressure upon the spinal cord and occlusion of the cerebro-spinal space are now easily ascertained by the increased protein in the stagnant fluid, and the exact site of the pressure can be made visible by the injection of lipiodol, which is opaque to x rays. By the constant discovery of changes in the protein content of the cerebro-spinal fluid and by the presence often of large numbers of cells therein, our whole conception of peripheral neuritis has been changed from that of an affection of the peripheral nerves to that of a malady creeping upwards along those nerves into the roots and central nervous system. Lumbar puncture has shown that spirochaetal infection of the nervous system occurs at quite an early stage, and this infection often dies out. Those subjects in whom signs of infection persist in the cerebro-spinal fluid are alone liable to the advent in after years of general paralysis and locomotor ataxy, and in the early treatment of such patients with malarial infection, mercury, and arsenic we have, we think, a certain means of stamping out altogether these terrible diseases from the community.

The "Encaged" Virus

Von Economo in 1921 conceived of a virus which, gaining access to the nervous system by the exposed olfactory terminals of the nose, becomes an "encaged" virus within the nervous system with no means of getting out, and which, if not conquered by the natural processes, might remain indefinitely to cause either recurrences of symptoms from time to time or, alternatively, progressive degeneration and death of the nerve elements. On this hypothesis he would explain the varying results of lethargic encephalitis—now a permanent cure, now a series of recurrences, and often again an advancing and resistless break up of nervous function long after the initial infection and when the primary symptoms had been slight. He would explain the absence of case-to-case infection in lethargic encephalitis and in poliomyelitis as due to the fact that the virus is encaged by the time the symptoms appear and cannot get out to infect others.

Infection can only occur from carriers and in the pre-symptomatic period of these diseases when the virus is a surface saprophyte in the nose. Nicolau and Galloway at the Pasteur Institute have shown how the viruses infecting the nervous system travel along the nerve threads to the remotest parts of the nervous system, and that any peripheral nerve twig, if dissected out and placed in the nervous system of another animal, will cause infection. In the course of the universal spreading of the virus the remarkable brightly staining "inclusion bodies" in the nerve cells and the lymphocyte exudations along the nerve fibrils remain as evidence of its passage. This complete invasion of the nervous system may occur without producing any symptoms at the time.

In the case of one encaged virus—that of herpes zoster—it seems clear that a local lowering of vitality of part of the nervous system by reason of injury, exposure to cold, arsenic administration, and other causes, breaks the encagement, and the virus discharges outwards along the debilitated nerve to flower upon the skin in the characteristic shingles, and that flowering upon the skin is the

only means of continuing the species and infecting other members of the community. After that flowering the virus within the nervous system dies as does the annual plant in the garden after its flowering. But it may happen that the debilitated nerve along which the virus is able to discharge is a motor nerve, in which case the virus is unable to flower. It may, however, give rise to much commotion with lymphocytic swelling in the nerve, and this is undoubtedly the cause of many of the motor nerve paralyses for which we have hitherto had no causal pathology, the commonest being Bell's facial paralysis from exposure to cold. Von Economo's principle of an infection encaged within the nervous system, existing and producing changes, without causing symptoms or alteration of function perhaps for years, and finally destroying, is likely to bring important developments in the future. As a clinical fact it has been known for long years in the end-results of spirochaetal infection, unrecognized at its advent and symptomless perhaps for half a lifetime.

That disseminated sclerosis never appears before the age of puberty means, I submit, that it takes fourteen years or more for the pathological process to run before symptoms occur. A single transient characteristic sign of this disease, lasting but a few days, often appears as long as twenty-five years before the progressive relentless disability begins, and I suggest that the process of demyelination is all over and irretrievable as soon as the progressive symptoms are present. We are faced with the inevitable scarring which long progressive and symptomless demyelination must entail. We must find some means of detecting the subjects of this disease during the symptomless stage if we are to treat them successfully. It is a remarkable fact that while disseminated sclerosis affects the central nervous system indifferently and everywhere, its destructive potentiality falls upon the younger elements of the nervous system only, those that have been recently acquired—namely, the pyramidal path, the co-ordinating mechanism for the upright stance and the finer movements of the hands, and for the recently acquired function of speech. The older functions of the special senses with touch, pain, and temperature are never progressively destroyed.

Louping-ill in Sheep and Benign Lymphocytic Meningitis in Man

Recently accident has revealed a principle which may have an important bearing upon neurological discovery in the near future. A virus expert was working at the Lister Institute upon the disease of sheep which is called "louping-ill" or "staggers." This is a virus disease, which, entering by the usual nasal route, passes along the nerve threads to the cerebellum, and there kills every nerve cell while leaving the rest of the nervous system entirely unharmed. One day this pathologist became severely ill with acute meningitis, which was supposed at first to be tuberculous, but from which, however, he made a complete and rapid recovery. He went to America to carry on his researches upon louping-ill. Shortly afterwards two of his co-workers and two of his laboratory assistants were seized with severe acute lymphocytic meningitis, from which they rapidly recovered, and it was proved from the serological reactions and by infection of animals that the recoverable meningitis in man was due to the same virus which caused destruction of the cerebellum in sheep.

The principle is that an infection in an animal which gives rise in that animal to a definite and incurable disease may produce in man an entirely different and curable disease. We already had this principle demonstrated in the opposite sense in the virus of herpes febrilis, which in man produces an insignificant event but

when introduced into the rabbit is apt to produce a fatal inflammation of the nervous system. Nervous diseases are common in animals, and it is to the closer association of veterinary and human neurology, and the wide investigation of the two together, that we look with hope to the discovery of cause and treatment in those common nervous diseases which are at present entirely mysterious.

Toxic Absorption and Neurology

The origin of disease and of tissue degeneration as the result of toxins from bacterial infection has entirely dropped out of neurology, except in the cases of the three exotoxins of tetanus, diphtheria, and botulism, which differ entirely from the elusive factor in what is commonly referred to as toxic absorption, in that they are real, they can be isolated and put in a bottle, and their effect proved by experiment. A few years ago the origin of pernicious anaemia and of subacute combined degeneration of the spinal cord in toxic absorption from intestinal infection seemed to have good foundation on clinical and experimental grounds, but subsequent discoveries in gastric and hepatic function have swept all such ideas away, and have introduced a deprivation origin for these diseases with highly successful means for their prevention and amelioration. Toxic absorption, at present much spoken of, will probably be similarly discarded from other realms of medicine within reasonable time.

It is highly interesting that the exotoxin of tetanus, by entering into combination with the protoplasm of the nervous system, does produce a train of events identical with that of the virus of hydrophobia, by living within the nerve protoplasm; in one case the highest degree of over-function in the fatal spasm, in another a complete loss of function in the toneless paralysis just like that of severe peripheral neuritis. It is probable that the many conditions of peripheral neuritis, at present without known cause and which seem to be increasingly common among us, may be due to virus infection, and the relapsing tendency after partial recovery is like the behaviour of an encaged virus. The difficulty in this investigation is the discovery of a susceptible animal, without which we cannot find or prove a virus as the cause of disease.

Deprivation conditions are likely to prove a fruitful field in the development of our knowledge of the causes of nervous disease. We have already established that tetany, subacute combined degeneration, beri-beri, and pellagra are due to known deprivations. The pigeon fed on polished rice, and therefore paralysed almost to death, which can be restored to complete strength and action in an hour by the administration of a few drops of infusion of rice husk, is a miracle of the effect that vitamin shortage and vitamin administration can make within the nervous system. It has recently been suggested that disseminated sclerosis may prove to be a deficiency disease.

The recent discovery of Sir Henry Dale that efferent stimuli in the vegetative nervous system produce their effect by the liberation of a chemical intermediary of the choline group, and that stimulation of the sympathetic in otherwise denervated skeletal muscle results in tonic contraction, seems to me to open up the possibilities of great advance in our very scant knowledge of the pathology of the myotonias, myasthenias, and myopathies.

In the progress of neurology the all-essential labours of the physiologist and of the anatomist have almost reached finality. Much addition to the wealth of their discoveries is not to be expected in the future. The bacteriologist, similarly, seems to have added all that is possible from his researches. Not even the absorption of hypothetical toxins troubles us as a factor in the causation of nervous

disease. The clinician and his inseparable pathologist have at the present time a fertile field where regional diagnosis has become well-nigh perfect in which to carry on the separation begun by Thomas Parkinson a century ago, and to show the easy recognition of new and distinct nervous diseases. Thus the thirty years of the present century have given us subacute combined degeneration, dystrophia myotonica, amyotonia congenita, epiloia, Schilder's disease, narcolepsy, the meningeal haemorrhages, the cerebral aneurysms, the many pituitary syndromes, and other distinct and easily recognizable maladies. It is astonishing how much more common a malady becomes when it has once been well described. There is scope for a rich harvest in the future, especially in the realms of peripheral neuritis, the muscular atrophies, and the vascular diseases. The virus worker and the biochemist have probably the greatest immediate future before them, heralded by their collection of the plums of the immediate past in their researches on poliomyelitis, tetany, pernicious anaemia, and insulin. The closer association between botanical, veterinary, and human medicine which has made a beginning will, I think, have an outcome in much advance, for nervous diseases are common in animals, and have not received sufficient attention.

The psychiatrist struggles with his most difficult burden of advance almost alone. The anatomist, physiologist, bacteriologist, virus worker, and biochemist have not, as yet, done anything material to clear the path for his progress as they have for the neurologist. Just as the highest functions of the nervous system allow of no physiological or anatomical analysis, so do its disorders at present admit no pathological and causal conception. The primeval forest of psychiatry, with no pathways cleared to look around, is hard beset with an ever-growing jungle of intricate terminology. The progress of neurology in my lifetime has been amazing, and its present position is highly advanced for a civilization which Sir Grafton Elliot-Smith insists is not yet sixty centuries removed from primitive man. And yet I doubt not that neurology has but made a highly successful beginning.

In his Harben Lecture on "The Diagnosis of Small-pox and the Investigation of Vaccinia by Laboratory Methods," delivered before the Royal Institute of Public Health on October 8th, Professor W. J. Tulloch, M.D., laid down five points which should be emphasized to members of the medical profession, and by them to the public. (1) Vaccination gives complete protection against both small-pox major and small-pox minor for several years, and partial protection for the greater part of the span of life. (2) The real value of the procedure as far as the individual is concerned is that it protects against small-pox major. So far as the community is concerned its value as a protection against small-pox minor is not unimportant; for the control of the minor malady is sometimes rather costly to local health authorities. (3) There is a potential danger at least that small-pox major may gain a footing at any time in this country. (4) We owe a debt of gratitude to the neighbouring countries which do enforce compulsory vaccination. It is significant that this measure is rigidly enforced in those European lands—Bulgaria, Czechoslovakia, Austria, and Hungary—whose geographical position is such that the disease may be introduced from the East. (5) The danger of grave complications following vaccination, notably encephalitis, is very slight when the procedure is performed early in life, but it is by no means negligible when primary vaccination has perforce to be carried out during the school years. In the absence of universal and compulsory vaccination, accurate methods of diagnosis in doubtful cases constitute a valuable addition to our armament for limiting the propagation of the disease.

IMMUNIZATION IN THE PREVENTION
OF SPECIFIC FEVERS*

BY

R. A. O'BRIEN, M.D., D.P.H.

From a recent paper I note with some, perhaps forgivable, tendency to a breach of the tenth commandment that when Dr. W. H. Park in New York wishes to compare the relative values of different methods of immunization—for example, by toxoid, given in different doses at different intervals, and with or without the addition of alum—he first investigates the problem, as we do, with laboratory animals, and then repeats the same investigation simultaneously on large groups of comparable children in schools—an opportunity which we in England can regard but with envy. Our English evidence has more of the "before taking" and "after taking" flavour.

Immunization in Diphtheria

Dudley recently recorded that before active immunization there were at the Greenwich School about forty-three cases of "diphtheria" each year, while in a comparable population, after immunization was adopted, the notified cases of diphtheria averaged eight each year for five years; of these cases only eight were clinically recognizable as diphtheria, and in six of them the boys were not yet inoculated. Our own endeavours enabled us to say that from 1921 to 1932 we had kept almost entirely free from diphtheria a school of about 600 children in which twenty cases had recently occurred. Similarly, it has been possible to keep the nursing staff of a large hospital almost entirely free from diphtheria for some five years, without causing any interruption of duty owing to reactions. Two years ago Dr. Parish showed that with toxoid he could produce within about six weeks a state of complete Schick-negativity in 95 per cent. of children in a home, and an appreciable immunity in another 5 per cent.: thanks to the Moloney-Fraser intradermal toxoid test immunization could be carried out without interference with school work. Those who wish to consider what has been done in England will find the details abundantly recorded in Dr. Forbes's book.

If we look at the recent past we find that reasonably good immunity was obtained by the "mixtures" toxin-antitoxin or toxoid-antitoxin, and the first sound evidence that immunization on the large scale was practicable was provided by these prophylactics. At present the "mixtures" are gradually losing favour, except toxoid-antitoxin floccules (T.A.F.), which apparently contains "pure" toxoid precipitated with serum globulin and is free of other "non-specific" substances. At all events, it very rarely causes "reaction," and is the antigen of choice for people who show a positive Moloney-Fraser reaction.

TOXOID AND ALUM-TOXOID

Toxoid alone is being more freely employed all over the world, and on the large scale in Canada. In Europe and the U.S.A. it has been found to make well over 90 per cent. of Schick-positive reactors negative when given in three, or even two, well-spaced doses. Toxoid is apt to cause troublesome local reaction, except in very young children, but this tendency is being circumvented in several ways. Some workers administer a full dose of 1 c.cm. to all children under 5, and at this age troublesome reaction is rare. For older children the Moloney-

Fraser intradermic test may be applied: the full dose of toxoid is injected into the Moloney-negative reactors and T.A.F. into the Moloney-positive. A good plan is to give what we have called the "universal" dose to all children—for example, 0.1 c.cm. or 0.05 c.cm. Dr. Chesney of Poole injects all children with a small "detector" dose to identify those likely to suffer reaction after inoculation. Toxoid combined with an immobilizing agent—for example, alum—is also being much used. Innocuous tapioca has been demonstrated by Ramon to have the same property—that is, of causing a retention of the toxoid locally over a long period. Glenny and Buttle showed that the tissue at the site of inoculation when excised some days later and injected into another animal immunized this second animal, and recent American evidence indicates that toxoid may be present in the local "lump" for a much longer period, during the whole of which it is being slowly absorbed and is producing immunity.

What of the future? Alum-toxoid—a discovery made by Glenny, Pope, Waddington, and Wallace—has recently attracted the deep interest of the medical public: the antigen has proved of remarkable service in animal immunization in the laboratory, but I am not yet wholly convinced that it will, for human immunization, displace formol-toxoid, which in two well-spaced doses immunizes rapidly. Apparently in certain "sensitive" children there is a liability to reaction due to the remaining non-specific materials present in the toxoid, as well as the tissue reaction or induration caused by the foreign body, alum, or a complex, alum-toxoid. In the U.S.A. special regulations have been framed for ensuring the potency and other requirements of alum-toxoid, but it is understood that the possibility of a reaction is giving the responsible authorities some concern. C. G. Pope has tested intradermally and subcutaneously in guinea-pigs a number of precipitated toxoids kindly supplied by American colleagues and in wide clinical use. While the tendency of different preparations to cause local reaction in the animal varies considerably, the evidence does not suggest that the American preparations provide better results in this test than some of our own, which seem to be attended by an undesirably high incidence of reaction in the limited number of human observations hitherto open to us. These persistent "lumps" and rare "sterile abscesses" still disturb the picture. C. G. Pope has recently carried out a long examination of the phenomena which happen when various percentages of alum are added to toxoid under different conditions, and has prepared precipitates with a minimal content of alum but a very high toxoid content. The work is promising, and is being pursued.

If we had clinical opportunities we should much like to test whether we can immobilize toxoid for a sufficient period in the tissue with substances less irritant and more absorbable than alum, which would slowly release the toxoid and maintain antigenic stimulation for a sufficient period.

SPECIFIC AND NON-SPECIFIC SUBSTANCES

What are our further aims? When the diphtheria bacillus grows in broth there are finally present at least three substances, or groups of substances, which must be dealt with before the ideal immunizing prophylactic can be prepared:

1. The first is specific toxin. This, as we know, can be turned into harmless but antigenic toxoid by various agencies, the most convenient of which is formalin, producing the well-known toxoid called "formol-toxoid," or, on the Continent, "anatoxine."

2. Secondly, there are a large number of "non-specific" substances—for example, various proteins, amino-acids, salts,

* Read in opening a discussion in the Section of Public Health at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

etc.—in the original broth, and also others of the kind produced by the metabolism of the growing diphtheria bacillus. Many attempts have been made to get rid of these substances. By precipitation, by dialysis, etc., most of the nitrogen can be removed. My colleagues, Mr. Pope and Miss Llewellyn Smith, made toxoid containing only 2 per cent. of the original nitrogen per Lf unit. By modification of the alum method of precipitation, elimination of nitrogen-containing bodies can be carried still further.

3. Thirdly, it almost appears as if the diphtheria bacillus, when building up molecules of specific toxin, gives rise to, as part of the same molecule, another substance undestroyed by heating, which in certain individuals causes the well-known "pseudo-reaction." If this supposition is correct we shall not entirely abolish the liability of unusually "sensitive" people to local and general reactions after the injection of any diphtheria prophylactic unless we can deprive the diphtheria toxin molecule of this "pseudo" constituent, for apparently the same substance, or complex, causes the "pseudo" reaction, the positive reaction in the Moloney-Fraser test, or the local reaction in the "anatoxi-reaction" described by Ramon, and the troublesome local and general reaction which may follow the injection of prophylactic. This supposition is reasonable, for the percentages of people showing these three phenomena are related.

When the chemist can make pure crystalline toxin as he now makes ferments and vitamins we can expect more rapid progress. The biochemist is making always "purer" toxin and toxoid. Jensen has prepared concentrated toxoid of high Lf value. C. G. Pope kindly allows me to say that by absorption methods he has recently prepared a toxin with a very much smaller nitrogen content per L+ or Lf than he has ever previously succeeded in doing. Further progress along these lines is eagerly awaited. I believe that until we can eliminate the "pseudo" constituent we shall not bid glad farewell to the local swelling and general malaise which may follow inoculation in certain people. Before leaving this aspect of the subject I may be pardoned for again calling attention to the efficiency of the method of dealing with an institutional epidemic which was described in 1923 (*Brit. Journ. Exper. Path.*, 1923, iv, 29)—that is, Schick-test and swab everyone; immunize immediately the Schick-positive children; and isolate and examine daily the Schick-positive and swab-positive children, for it is in this group that you will catch all the cases of diphtheria. (Within the past twelve months we have a record that diphtheria attacked more than one-quarter of the nursing staff of one moderately large hospital.)

TYPES OF DIPHTHERIA BACILLUS

The interesting investigation of the "gravis" and "intermediate" types by McLeod and his school suggests the question, Will our current methods of immunization secure immunity against all types of diphtheria? Robertson and Marshall in their Manchester work recorded eight cases of the throat affection long ago described by Harries as "tonsillitis in Schick-negative carriers"; they also recorded one "severe" and three "moderately severe" infections with gravis bacilli in people recorded as Schick-negative. (the full immunological data were not reported). Dudley's exhaustive work at Greenwich suggests that the Schick-negative condition produced by immunization with the ordinary prophylactics gives a slightly lower degree of immunity against gravis infections than against mitis, but his conclusion is that, even in infection of the throat of a Schick-negative child, the clinical result is usually trivial. Further, Parish injected a considerable number of gravis cultures, in fatal doses, into more than fifty guinea-pigs which had been rendered Schick-negative by the ordinary prophylactics of various kinds, and found that the animals

were immune. In "field trials" on huge numbers of human beings in America, Canada, and on the Continent, prophylactic made from the classical Park-Williams S strain seems to have given adequate protection. We are justified, therefore, in the absence of other evidence, in directing all our efforts at the moment towards an improvement of the type of prophylactic hitherto made from the Park S strain.

IMMUNIZATION AND THE CARRIER RATE

Has inoculation any remote effect on the uninoculated? Dudley has recently recorded that, following immunization of part of a group of boys in the Greenwich School, the "virulent carrier rate" rose, and therefore the risk of attacks of clinical diphtheria increased for those not yet inoculated. Dudley, with his characteristic caution, warns against assuming that this phenomenon would happen generally. I was naturally deeply interested in this suggestion. I believe I am right in saying that a similar argument was at one stage urged in opposition to the proposal to introduce antityphoid inoculation in India and elsewhere, and that experience provided no justification for the argument.

We had ourselves, in several instances, watched a small group of people during immunization, and had seen no indication of increased danger to those not yet immunized. I wrote to a number of leading authorities in the U.S.A. asking what their experience had been, and received permission from E. S. Godfrey and W. W. Lee and others to say that they were impressed with the fall which follows immunization, and that, so far as their experience and consideration of American figures formed a guide, they found no evidence that the morbidity or mortality rises even temporarily in a partly immunized community because of the suggested rise in carrier rate among the inoculated. I know that some other leading authorities in the U.S.A. hold the same view. I may here refer briefly to a recent review by Das. It has always been something of a mystery that clinical diphtheria is so rare in tropical countries. The Schick-negative rate is high and the virulent carrier rate seems to be substantial, yet diphtheria rarely occurs among either natives or introduced Europeans. There is no indication that by any laboratory test the bacilli existent in these regions differ in any way from those causing severe and fatal diphtheria in temperate countries. These still remain something to explain.

Scarlet Fever Immunization

In connexion with immunization against scarlet fever, there is, unfortunately, little new to report. Active immunization with a small series of doses of toxin gives high protection against scarlet fever. J. G. Fitzgerald (*Canadian Pub. Health Journ.*, 1933, xxiv, 455) found that, since all Dick-positive nurses at the Children's Hospital, Toronto, have been regularly immunized, the incidence of scarlet fever has been from 0.4 to 0.7 per cent., whereas previously it was from 5 to 6 per cent. It will be remembered that Harries and Benson in this country supplied similar satisfying evidence a few years ago.

Several workers have aimed at shortening the tedious course of four or five injections. In 1929 Ramon and Debré (*Compt. Rend. Soc. Biol.*, p. 1035) formalized toxin and injected children. The immunity obtained was moderately good, though the course could not be reduced to less than three injections, and reactions occurred in about half the children. From the absence of recent publications, it may be concluded that the method has not yet established itself. Ando and Ozaki, in the Dairen work, perhaps provide the clue. As the intensity of

formalinization is increased, the toxicity is reduced, but, unfortunately, so also is the immunizing efficiency. Veldee has studied the method extensively during the past few years. He inclines to the view that formalinization must not be carried too far; unless approximately 500 skin test doses of toxin per cubic centimetre are left, high immunity is not secured, even with three doses and with the addition of alum. Here again it must be pointed out that experience indicates that progress would be more rapid in England if opportunities for immunizing large comparable groups of children were available. R. A. Q. O'Meara and H. J. Parish kindly allow me to say that they have been working with toxin-antitoxin mixture and with floccules as immunizing agents, but the few results available do not yet warrant publication. G. A. H. Battle has been endeavouring to immunize rabbits rapidly by several modifications of the ordinary methods and by the use of the toxin of unusually high value described by O'Meara, but has not yet obtained results that satisfy him.

Whooping-cough

The work of Madsen in Scandinavia and Sauer in U.S.A. offers considerable hope. Madsen states that of 1,800 people vaccinated 25 per cent. escaped infection, whereas only 2 per cent. of 450 non-vaccinated people escaped. Sauer found that of 380 young children who were vaccinated and suffered exposure not one became infected. An odd feature is that, while Madsen finds that children rapidly become immune, Sauer does not expect adequate immunity to develop for about four months. Jundell in Sweden vaccinates adult volunteers who have had an attack in the past, and hopes in this way to raise the titre of the antibody in the blood, thus obtaining an equivalent of the invaluable "convalescent measles serum" for protection of groups of young children in contact with sufferers from the disease.

General Note

Two thoughts may occur to the practitioner who is interested in this field of work. Reflecting on the resistance of the average parent to vaccination in any form, he will perhaps conclude that if the enthusiast gets his way there will be too much immunization. He must then remember that diphtheria alone causes 40,000 to 60,000 cases a year in England and 2,000 to 3,000 deaths, and that if we adopt Dr. Glover's estimate of the loss of time due to infectious disease in large schools the lost educational time must cost the community a huge sum each year.

The second thought will probably be one of some regret that progress is so slow. The lag is almost wholly on the human side. The immunologist, in England at all events, is always far ahead of the clinical investigator; with greater opportunity of using, under proper safeguards, different antigens on large groups of children, we should progress faster.

G. Serdaris (*Thèse de Paris*, 1934, No. 64) describes the antimalarial campaign carried out in a period of six months in a small area (Rhododaphnia), of the Peloponnese under the auspices of the International Health Division of the Rockefeller Foundation and the School of Hygiene of the Athens Ministry of Health. Although a definite opinion cannot be expressed until the end of three years, the results hitherto obtained have been very good. The number of *A. maculipennis* and *A. superpictus* has considerably diminished, and the splenic index has decreased, while the haematological index has increased. Quinine salts only were used for treatment.

IRRADIATION TREATMENT OF MALIGNANT INTRATHORACIC TUMOURS

BY

CHIEF ASSISTANT TO A MEDICAL UNIT, ST. BARTHOLOMEW'S HOSPITAL;
PHYSICIAN, ROYAL CHEST HOSPITAL

In September, 1927, one of us (F. G. C.), with Dr. Carlyle Potter, published a follow-up of cases of malignant intrathoracic tumour treated by x rays.¹ The results were most discouraging, for out of fifty-nine cases one alone survived. The result in this case, however, was so remarkable that it was impossible to do otherwise than encourage further trial and further development of the treatment. The patient, a young woman aged 25, was under the care of Lord Horder in St. Bartholomew's Hospital in 1923. She was desperately ill with a large mass in the mediastinum, many large glands in the neck, and bilateral pleural effusion. Microscopical examination of a cervical gland showed lymphosarcoma. She still survives in excellent health, and the skiagram is absolutely normal.

The authors of the article were unable to report any prolongation of life, apart from this one instance, and only temporary or no appreciable alleviation of symptoms. In the last few years, however, the results from treatment have seemed to the present authors to be better. Many impressive cases of relief of symptoms have been noted, and also the complete disappearance of the mass in the chest in several instances. It seemed desirable, therefore, to make another investigation into the results of treatment in a series of more recent cases.

Diagnostic Criteria

The first criterion is the proof positive—namely, microscopical examination of a section of the thoracic growth or of a metastasis. This must be accepted as the most convincing evidence, in spite of occasional difficulties of interpretation. The material for examination has been obtained by thoracotomy in seven cases, by bronchoscopy in seven cases (this excludes cases subsequently confirmed by post-mortem examination, otherwise the number would be larger), by removal of a metastasis in five cases, and from post-mortem material in nineteen cases.

The second criterion is clinical evidence: symptoms, signs, course of the disease, and exclusion of other conditions by special investigations. The third is radiological evidence.

It would occupy much space if we attempted to elaborate the last two criteria, nor is it perhaps quite within the scope of this paper. We can say, however, that no doubtful case has been included, and we are confident that the rigid criteria adopted would be accepted by all workers as adequate proof. The few difficult or doubtful cases are described in some detail later.

Our material consists of seventy cases from St. Bartholomew's Hospital, the Royal Chest Hospital, Victoria Park Chest Hospital, and private practice, from 1927 to 1932.

We are indebted to the following physicians and surgeons:

Dr. Geoffrey Bourne, Professor Langdon Brown, Drs. J. B. Christopherson, E. H. Colbeck, E. R. Cullinan, Geoffrey Evans, H. Morley Fletcher, Professor Fraser, Drs. E. A. Gow, G. Graham, Sir Percival Horton-Smith Hartley, Dr. R. Hilton, Lord Horder, Drs. C. M. Hinds Howell, D. Barty King, A. J. Scott Pinchin, Arnold W. Stott, H. E. Symes Thompson, F. E. S. Willis, W. B. Wood.

Sir Thomas Dunhill, Professor Gask, Sir Charles Gordon-Watson, Mr. L. B. Rawling, Mr. J. E. H. Roberts, Mr. H. G. B. Russell, Mr. R. M. Vick.

The cases presented are as follows:

	Cases
1. Bronchial carcinoma treated by x rays ...	44
2. Bronchial carcinoma treated by radium or radium emanation ...	12
3. Malignant tumours other than bronchial carcinoma treated by x rays:	
(a) Primary in the chest ...	2
(b) Secondary carcinoma ...	5
(c) Secondary sarcoma ...	2
4. Tumours of doubtful nature ...	5

In each of the cases treated by x rays at least ten applications were given. In a great number of other cases treatment was abandoned in the early stages of the course, and these have been excluded from this series.

Treatment by Irradiation

It must always be assumed in dealing with neoplasm of the lung that the glands of the mediastinum are involved or are likely to be involved, and must therefore be thoroughly treated. Lymphosarcoma requires a much smaller dosage than carcinoma and endothelioma. Occasionally the early treatments can only be applied from one or two directions owing to the patient being too ill to be moved. Later in the treatment, as the patient improves, other ports of entry can be used. The treatment is spread over two, three, four, or five weeks, and is given on five or six days each week.

Principles of Treatment

1. To give a sufficient dose to the whole growth and to the lymphatic glands likely to be affected.
2. Without restricting the dose on the growth, to give as small a volume dose to the general tissues of the patient as is consistent with efficient dosage to the tumour and lymphatic glands.
3. To damage the lung as little as possible. Lung which has been the site of old inflammation, tuberculous or otherwise, is very radio-sensitive, and exacerbation may result.
4. To cause no damage to the skin beyond a severe erythema, which ultimately clears up. With lymphosarcoma only a mild erythema will be necessary, but with carcinoma a severe erythema verging on blistering is usually required.
5. Some workers, including one of us (N. S. F.), consider lipiodol undesirable in a lung which is to be subjected to irradiation, on the ground that residual lipiodol gives out secondary radiations of long wave-length, which cause damage and necessitate curtailment of the requisite course of treatment.

Technique of Treatment

Various techniques have been used in our cases. As a rule a number of ports of entry are employed, but occasionally, with a very radio-sensitive tumour, only anterior and posterior fields are necessary. Various different plans have been used according to the situation of the growth: if in the anterior part of the mediastinum, a number of relatively small ports of entry are used converging on the

mediastinum; but, if the growth extends far into the lung, larger fields are usually employed—generally four—at an angle of 45 degrees to the direct anterior and direct posterior; taking in both the lung growth and the mediastinum, and decentred towards the side of the growth. In other cases, where the growth is almost entirely on one side and far into the lung, a direct anterior and posterior field is used, slightly to one side of the middle line, and this is supplemented by a lateral field on the affected side.

In most cases the filtration has been about 0.5 mm. of copper and 1 mm. of aluminium, and 180 kV continuous current on the tube, but in our later cases a Thoraeus filter has been used, which is equivalent to about 2.7 mm. of copper, with 200 kV continuous current, and at the present time we are using for our private cases an even higher voltage, up to 300 kV Villard circuit current with a filter of 0.6 mm. tin + 0.25 mm. copper + 1 mm. aluminium, equivalent, with the wall of the tube, to about 4 mm. or more of copper. With the increase in filtration the number of roentgens (r) to produce an erythema dose increases considerably, and the number of roentgens necessary on the growth also increases.

For a lymphosarcoma or a very radio-sensitive tumour it is necessary to give about 150 to 180 per cent. of an erythema dose, spread over a fortnight; a larger dosage must be given if it has to be spread over a longer period, owing to the patient not being able to tolerate the ordinary dose at first.

With a carcinoma of the lung or resistant growth, about 250 to 300 per cent. is given, spread over a month or six weeks.

The erythema dose we reckon with 0.5 mm. copper and 180 kV is 650 roentgens: the erythema dose with a filter equivalent to about 0.4 mm. of copper and 300 kV is approximately 1,000 roentgens.

Effects of Treatment

It is always difficult to reach a definite conclusion as to the results of any particular line of treatment, and care must be taken in assessing the results. This difficulty applies particularly in the case of bronchial carcinoma, because the criteria of improvement are difficult to define on account of the well-known spontaneous variation of symptoms. In the first place there may be obvious clinical relief of urgent pressure symptoms; secondly, the effect of treatment on the size of the tumour may be observed in serial skiagrams; and lastly, the result as regards the duration of life may be considered.

The first of these criteria is a matter of clinical observation. In calculating the size of the tumour on the x -ray film only very gross changes should be admitted, for the direction and penetration of the rays may cause minor apparent changes which are of no great significance. We therefore propose, in judging the effects of treatment on the size of the tumour, only to include cases in which the shadow has practically disappeared. Finally, the duration of life from the date of the beginning of treatment may be considered; the advantage of this is that it provides a fixed point from which calculation may be started, and it is thus more definite than calculations which are based on the total duration of symptoms, in which case no very definite point of commencement can usually be fixed.

The forty-four cases of bronchial carcinoma treated by x rays can be divided into the following groups:

1. *Cases which Showed Great Improvement.*—Twenty-three cases are included in this group; primarily on the ground of symptomatic benefit. In ten of these relief of pressure symptoms was rapid and the result dramatic. In eleven there was gradual improvement over a period

of weeks. In the remaining two cases the shadow in the x-ray film disappeared, but it is noteworthy that there was little or no improvement in the condition of the patient. Serial skiagrams showed almost complete disappearance of the shadow cast by the primary growth in nine cases, and complete re-expansion of a collapsed lung in two cases. The ultimate fate of the cases is as follows: five are known to be alive at the time of writing, thirty-two, thirty-one, twenty-four, six, and five months respectively after the commencement of treatment. In the first three of these cases it is probable that life has been greatly prolonged in addition to the symptoms being relieved; in one of these the diagnosis has been confirmed histologically. The remaining eighteen patients are all known to have died, and the average duration of life after beginning treatment was 9.7 months. Only three patients survived more than fifteen months, dying respectively in thirty-six, seventeen, and sixteen months.

2. Cases which Showed Slight Improvement.—In seven cases there was incomplete but definite relief of symptoms, and in this group the average duration of life was 8.6 months. The fact that the average duration of life in these two groups is about the same would appear to suggest that great symptomatic improvement or disappearance of the shadow in the skiagram does not necessarily indicate prolongation of life.

3. Cases which did not Respond to Treatment.—In fourteen cases there was no change in the condition of the patient after a course of treatment. In two, the date of death could not be ascertained; the average duration of life in the remainder was 5.4 months.

It does not seem that x-ray treatment has any great effect in prolonging life in this disease, except possibly in rare cases; it is quite definite, however, that this treatment can relieve the more urgent and distressing symptoms in about two-thirds of the cases, and can cause local disappearance of the tumour. In our opinion there is sufficient evidence of symptomatic improvement to justify the adoption of this line of treatment in all cases in which obstructive or irritative symptoms are present. The changes in the size of the tumour, as demonstrated, are sufficient to justify the hope that improvement in the technique of treatment will in the future yield greatly improved results.

4. Cases Treated by Radium.—In ten cases in which radium or radon was introduced directly into the growth through a bronchoscope the average duration of life after the operation was 2.4 months. In no case was any dramatic improvement recorded, and, in two, death resulted from haemorrhage shortly after the operation had been carried out. The results in this series are therefore definitely discouraging. In two further cases radium was inserted into the tumour through the chest wall. In one of these marked temporary diminution of the tumour occurred; in the other there was decided improvement in the general condition of the patient for a few months; death occurred eight months after the operation.

Other Intrathoracic Tumours.—Nine cases of malignant tumour other than bronchial carcinoma are included in this series. This group is composed as follows:

Secondary hypernephroma	2 cases
Primary sarcoma	1 case
Secondary sarcoma ? appendix	1 ..
Secondary sarcoma ? bladder	1 ..
Secondary carcinoma breast...	1 ..
Secondary sarcoma fibula	1 ..
Secondary carcinoma thyroid	1 ..
Endothelioma ? from thymus	1 ..

In four cases the treatment did not appear to have any effect. In two cases, secondary to hypernephroma and to carcinoma of the bladder, haemoptysis appeared to be controlled by irradiation; the intrathoracic deposits in the case of sarcoma of the fibula diminished greatly in

size under the treatment, and the cough was much relieved.

The remaining two cases are remarkable in that the patients are alive eleven and twenty-one years respectively after treatment.

The first was a patient under the care of Sir Thomas Dunhill and Dr. Thursfield. A mediastinal tumour was present, causing breathlessness, swelling of the neck, distended veins over the back and chest, shoulders, and arms, and a gland or prolongation of the tumour in the right supraclavicular region. A sternal flap was made and the tumour exposed. This was thought to be an infiltrating sarcoma, and nothing more was done. Microscopical examination of the portion removed revealed an endothelioma of apparent thymic origin. Courses of x-ray treatment were commenced in August, 1923. The tumour entirely disappeared, and the patient is alive and well at the present time.

The second was also a patient under the care of Sir Thomas Dunhill. She was first seen in November, 1913, when a nodular goitre on the right side was removed. Section suggested malignancy. In 1918 a small nodule was removed from the extreme right edge of the scar. Section showed an almost solid mass of epithelial cells, resembling thyroid cells. The patient remained well until 1927, when a haemoptysis occurred (half a cupful). The skiagram at this date showed rounded nodules in both lung fields. These increased rapidly, until there were many nodules of a perfectly rounded shape in both lungs. X-ray treatment was therefore commenced in March, 1928. The haemoptysis ceased and the patient remained in good health, and has done so until the present day, although the nodules have grown in size and number.

Finally, there are five cases to be considered in which both the clinical picture and the x-ray appearance suggested malignant tumour, in which either cure or great relief has occurred. Unfortunately, in none of these cases have we histological proof of the nature of the mass. They are of such interest that they are worth describing in detail.

The first was a case included in the original follow-up in 1926. The patient, E. M., was under the care of Dr. Robert Hutchison at the London Hospital in 1924, with swelling of face and neck, and a shadow in the skiagram suggestive of growth in the right upper lobe. The diagnosis was malignant growth. X-ray treatment was given, and the patient made a complete recovery. He was seen by one of us (F. G. C.) in 1926, when it was thought that the original diagnosis was probably mistaken, and that it was a case of dense fibrosis and not malignant disease. It fortunately happened, however, that we were able to keep in touch with the after-history of the case. He died in 1933 of intestinal obstruction, when a columnar-celled carcinoma of the descending colon was found post mortem, and, through the kindness of Dr. W. Smith, we were able to obtain the result of the examination. There was marked dilatation of the azygos vein, there were universal pleural adhesions on the right side, and a firm mass was present at the hilum of the right lung, about two by one and a half inches in size. Some fibrosis was present in the lung itself. Section of the mass showed merely much fibrosis with round-celled reaction. The pressure symptoms originally suggested malignant growth of the lung. We can make no further comment.

The second patient, a woman aged 34, was under the care of Lord Horder and one of us (N. S. F.) in 1930. The skiagram showed an enormous mediastinal mass, extending into and occupying most of the left lung field. This was treated by x rays, and the entire mass disappeared, and the patient is alive and well to this day. There must remain a doubt whether this was a primary mediastinal lymphadenoma or a lymphosarcoma.

Case number three was a man aged 57, seen by one of us in 1930, at the City of London Chest Hospital, Victoria Park. The patient complained of cough, shortness of breath, loss of weight, and haemoptysis. There was clubbing of the

* There has been a recurrence in this case in May, 1934. It has again been treated by x rays and the shadow has again disappeared, and there is now no evidence of disease.—N. S. F.

fingers. The skiagram showed a dense mass filling the whole of the right upper lobe. Exploratory thoracotomy was performed by Mr. Romanis, when a large inoperable "growth" was encountered. Unfortunately no piece was taken for section. It was assumed to be a carcinoma, and the operation was abandoned. He was then transferred to St. Bartholomew's Hospital, where he was given twenty applications of x rays. The mass almost entirely disappeared, leaving considerable fibrosis. The patient is still alive and well, but the nature of the mass remains in doubt.

The fourth case was that of a lady aged 55, seen privately (F. G. C.) first in July, 1932. There was pain in the back and shortness of breath and loss of weight. She had been fairly well until a year previously, when the symptoms commenced. When first seen the patient was extremely ill, with dyspnoea, stridor, and slight clubbing of the fingers. There was intense dullness over most of the left side, almost down to the base, where she was resonant, and where breath sounds were present. Over the dull area breath sounds were absent and vocal resonance diminished. There was a loud surging murmur to be heard in the second intercostal space. She was explored deeply on two or three occasions, when pure blood was obtained with great ease, the syringe rapidly filling. The heart was displaced away from the mass. She was so ill that an exploratory thoracotomy was considered to be unjustified by Mr. J. E. H. Roberts. The diagnosis was a large innocent tumour or a lymphosarcoma: Wassermann reaction negative. On going further into the history it was found that three years previously she had had severe pain in the left chest, which made her faint.

A full course of deep x-ray therapy was given, after which she made a most striking improvement, although the shadow remained unchanged. This improvement continued to December, 1933. The patient was able to take long walks and drive a car, and felt comfortable and almost free from symptoms. In December, however, she began to have choking attacks, and a further course of x-ray treatment was given. She was very ill both during and after this course, but is improving again, and able to lead an active life. The improvement in symptoms was most striking and dramatic, but again there was no change in the shadow. The nature of the tumour remains in doubt.

The fifth patient was a man aged 54, seen at Victoria Park Chest Hospital; he complained of pain in the right chest and axilla, much dyspnoea, loss of weight, and some cough. There was a large homogeneous shadow in the skiagram, occupying the middle zone of the right chest, and extending from the periphery inwards, almost touching, but not apparently involving, the hilum of the lung. The shadow looked like a localized pleural effusion. Several exploratory punctures were made, however, and no fluid was found. The Wassermann reaction was negative. It was regarded, therefore, as a malignant tumour, and twenty applications of deep x rays were given, from February to April, 1933. The tumour practically disappeared, and the patient is still alive and in reasonably good health. Within the last few weeks he has developed headache with papilloedema, almost certainly due to an intracranial metastasis.

Conclusion

There can be little doubt that since the publication mentioned at the beginning of this paper the results of x-ray treatment have improved very greatly. We have been able to quote many cases of great relief or complete disappearance of symptoms, and some where the undoubted malignant mass in the chest has entirely disappeared. While we cannot yet claim to have arrived at a cure, we have been able to quote two, and possibly three, cases in which this has apparently been obtained. In two instances, where the diagnosis has been proved beyond all manner of doubt, there has been a complete and lasting cure, but neither of these tumours was of bronchial origin.

In view of these conclusions we shall often be exercised, in making the decision, whether to advise this treatment to an individual patient or not. Relief from pressure symptoms can be expected in a certain proportion of cases, and if these are severe and distressing we can, hardly

deny the treatment if it is available. In other cases, in view of the unavoidable expense of the treatment or the inconvenience caused by moving the patient to an institution, and the impossibility of guaranteeing a result and the severe reaction that may be suffered during or shortly after the cessation of the treatment, we may find it very difficult to make up our minds. A decision may have to be left to the patient or to the relatives. This attitude will not hinder the progress and development of the treatment of carcinoma or other malignant tumours of the lung by radiation therapy, because there will always be a large number of patients who will demand active measures, and who, particularly in the early stages, will demand this or some other form of active treatment.

In conclusion, we must not forget the dramatic improvement in the individual case in surveying the final result of the treatment critically and dispassionately.

SPECIAL CLINICS FOR DIABETICS (ORGANIZATION AND EXPERIENCES)

BY

L. WISLICKI, M.D.

VICTORIA MEMORIAL JEWISH HOSPITAL, MANCHESTER

The organization required for prolonged treatment of diabetes has become of special interest, since, through the discovery of insulin, even severe cases of diabetes may be kept in a good condition permanently. Yet in actual practice, although the average duration of life among diabetics has increased (Joslin¹), periodic examinations have often demonstrated the results to be disappointing. According to Loewenberg and Noah,² one year and a half after discharge from the hospital only 10 per cent. of the patients were without glycosuria, and a large number showed increased fasting blood sugar or even acidosis. On extending his investigations over a period of six years, Reinwein³ stated that about 40 per cent. of the patients had died; of the remainder, 42 per cent. did not carry out the insulin treatment properly, and 28 per cent. admitted that they had not strictly adhered to the diet which had been prescribed for them. As a consequence, the largest Berlin panel organization (Allgemeine Ortskrankenkasse) found that the incapacity present among diabetics in most age groups was on the average twice as great as was the case among patients suffering from other diseases (Pryll⁴).

Some Causes of Unsuccessful Treatment

There are different reasons for the fact that the ultimate results in ambulatory practice are so unsatisfactory as compared with the success obtained through hospital treatment. The patients may find a certain diet which, although suitable while at rest in hospital, is insufficient while they are at work. By taking inadequate food they lower their tolerance, and the condition becomes worse, though very often exercises have a favourable influence on carbohydrate metabolism.

This has been proved by experimental as well as by clinical observations. After partial extirpation of the pancreas in the dog physical work diminishes glycosuria, but has no influence on it when the gland has been removed completely (Seo,⁵ Allen⁶). Correspondingly, clinical workers have found that in suitable cases exercises could improve the carbohydrate tolerance of diabetics (Trousseau,⁷ v. Noorden,⁸ Buerger,⁹ Allen, Stillmann, and Fitz,¹⁰ Hetzel,¹¹ Lawrence,¹² Joslin¹³).

Further, the condition of a patient may deteriorate if he is prevented by his profession or for any other reason from having his meals at regular hours. Disappointing results over a long period may often be due to the financial difficulties of the patient, causing him to neglect the treatment. Statistics have shown that disablement among diabetics depends to a great extent on their financial condition, the average duration of disablement being inversely proportional to the income (Pryll⁴). Patients are as a rule prepared to adjust themselves to a diet and to the demands of insulin administration, but lack of money leads to neglect of the treatment, then to a decrease in the carbohydrate tolerance, and to complications which may even endanger life.

Such relapses compel diabetics to undergo repeatedly a strict regime in hospital, because at home only a small number of intelligent and self-controlled patients will allow the physician to carry out the measures necessary in severe acidosis or in the complicating infections. Diabetics therefore become in-patients, not only for short control examinations, but also for longer treatment in order to regain a bearable degree of carbohydrate tolerance.

According to Pryll's statistics, the average stay in hospital for these patients is a rather long one. Likewise, Loewenberg and Noah state that 37 per cent. of their cases were in-patients for from one to three months and 9.5 per cent. for over three months.

Apart from the high expenditure incurred by the long stays in hospitals, the costs for the insulin became very high. For instance, in 1931, 155,000 prescriptions, covering 57 million units of insulin, were issued by British insurance practitioners.¹⁴ Therefore, for all organizations having a large number of diabetics under their care, the problem was to find a way to keep these patients in a good condition and, at the same time, to diminish the costs of treatment.

Several proposals have been made in an attempt to find a solution for the problems raised above. Lyon,¹⁵ Earl,¹⁶ Lawrence,¹⁷ Taterka,¹⁸ Rostocki,¹⁹ Gottschalk,²⁰ and others have written on the subject of clinics for diabetics. Joslin²¹ suggested the foundation of diabetic centres and the education of nurses, each nurse having eventually to take care of a large number of patients. v. Noorden²² considered periodical in-patient treatment to be useful for purposes of control. In order to combine dietetic treatment with individually adapted muscular work, Katsch²³ established a home for diabetics.

Certain essential conditions must be fulfilled in order to achieve a permanent success that is to establish in the diabetics a balanced metabolic condition. It is necessary to have regular medical advice, the diet must be adapted to changing circumstances, and it must be impressed upon the patient that his co-operation and self-control alone can lead to lasting good health.

With these ends in view, and in order to diminish, if possible, the expenditure for the treatment of the unemployed diabetics, I, together with Dr. Liebenow, stellvertretender Stadtarzt (municipal officer of health), organized a consulting clinic for a Berlin district of about 360,000 inhabitants, about one-third of them receiving unemployment benefit. The organization and the experiences dealt with in this report are concerned with these 120,000 unemployed people.

Organization of a Consulting Clinic

About 500 diabetics regularly attended the clinic held by the writer and his collaborators in a hospital of the district during three mornings in the week. All analyses were made in the clinic itself. Qualitative and quantitative urinary examinations were carried out at once, but

when the blood sugar was examined patients either waited for the results or attended the following session of the clinic. Two to three technicians were occupied in performing the chemical examinations, in dispensing insulin, and in secretarial services. A registration card was kept for each patient which gave clinical dates, the results of the analyses, and the prescriptions issued. A rapid survey of the condition of the patients could thus be obtained.

Dangerous cases—for example, gangrene—were taken to the hospital to which the clinic was attached. Patients attended at least once a month, but if minor cases were continually in a good condition they only came about every two months; on neglecting to come for control examinations they were communicated with by post. The practitioners of the district were instructed to send their unemployed diabetics to the clinic, and they received written reports on the findings of the clinic and concerning the prescriptions and instructions given. The work of the clinic was strictly limited to the investigation and the treatment of the metabolic conditions of diabetics. The practitioners were in continual contact with the clinic, and attended the patients in connexion with all other aspects of their disease, and with any other complaints from which they might be suffering.

Consultations

Every patient had to bring a sample of urine which had been collected during the previous twenty-four hours; some of them were asked to come while fasting for blood sugar examination, or, if necessary, for a sugar tolerance test. The basis upon which diets for diabetics are prescribed will vary according to the outlook of the physician conducting the clinic. He may prefer a diet rich in carbohydrates, eventually to be combined with large doses of insulin (Adlersberg and Porges, cf. Joslin), or a diet containing much fat and a minimum of protein and carbohydrates (Naunyn, Petren). He may believe that a restricted diet is a chief principle in diabetes treatment (Allen). All these forms of treatment can be carried out among out-patients.

As the patients of the clinic were of the poorer classes, the economic side of dietary prescriptions had to be considered. It must be borne in mind that the actual prices in different seasons vary to a great degree, some types of food being cheap in summer and expensive in winter, and conversely. We had therefore to change the proposed dishes according to the fluctuation in the actual prices. The patients received detailed dietetic instructions through leaflets drafted for this purpose, and each patient obtained also a diet sheet suitably prepared according to the needs of that particular case. Forms were given them which contained equivalents of the different carbohydrate foods, as well as combinations suitable for single meals and for a whole day's menu. Moreover, the costs for these dishes were calculated according to the market rates.

It soon became evident that the expensive diabetic diet could only be made available for necessitous people through some financial aid. The municipality not only assisted them by giving free treatment and medicaments, but also by contributing towards the cost of suitable foodstuffs. The scale of assistance given was based on thorough statistical calculation of prices of the foods necessary, and on the degree of severity of the disease and the requirements of the case. Patients requiring insulin were taught how to disinfect and to use their syringes. They received simple printed instructions as to the time relation between insulin administration and carbohydrate intake, as well as information concerning the signs of hypoglycaemia and how this can be avoided. When patients were unable to inject insulin themselves

they were treated at home by nurses. Visiting nurses also attended them when confined to bed, reported to the clinic, and delivered those samples necessary for examination.

The consultations were supplemented by a series of popular lectures explaining in full the subjects which could only be briefly mentioned during the consultation hours—for instance, the character of the disease, the general treatment and hygienic measures, the different types of diet, hypoglycaemia, and the various complications. In the hospital kitchen patients had the opportunity of learning how to prepare their diet.

Experiences at the Clinic

Some forty to seventy patients attended the clinic during a single session. Most of them came for control examination without having been reminded, and this was particularly so among the severe cases. A considerable number of those attending for the first time were in an unsatisfactory condition. Though receiving large doses of insulin, they often showed high glycosuria or acetonuria. This was caused by neglect of diet for the reasons explained above, or through faulty or erratic insulin administration, as well as through failure to observe the time relation between insulin administration and carbohydrate intake—in fact, this last point often caused the greatest difficulties. Generally the insulin consumption was high, as the patients often continued to use the amount originally prescribed although the tolerance had changed. Some patients had utilized their insulin rather carelessly through lack of supervision. Most of them, when doing muscular work, found it intolerable, both physically and mentally, to take less than four ounces of bread daily. However, when patients became aware that insulin does not cure the disease, but controls it, they usually made the required effort to adhere strictly to their dietetic prescriptions.

Experience has shown that in a great number of patients the form of diet had to be varied. For instance, we often found it necessary to include vegetable days, or, especially in cases with a tendency towards acidosis, an oatmeal day followed by a vegetable day, in order to keep patients in good metabolic condition. A great demand for explanations was apparent at the lectures, usually attended by several hundred persons. These lectures likewise gave a good opportunity for the lecturer to expose the remedies of quacks, so numerous in connexion with diabetes mellitus.

After considering the results of the regular and uniform treatment given within the relatively short time that the clinic existed, I feel justified in concluding that the initial aim of the clinic had been accomplished. Relapses in metabolic conditions occurred but seldom, and the tolerance improved continuously in many cases. This was also proved by the fact that no patient developed coma, although about one-third of all the cases were severe. Consumption of insulin decreased considerably owing to the improvement in the patients' condition as a result of the described method of medical supervision. The first 200 patients treated had previously received about 100,000 units of insulin monthly, but only about the same amount was required by the clinic for about 500 patients. A considerable monthly saving, amounting to several hundred marks, was also made by the purchase of insulin in large quantities. For instance, the price which the clinic had to pay in February, 1933, varied from 45 to 60 pfennigs for 100 units, while previous to its existence insulin was purchased at retail prices (about double the cost). Even in severe cases the adjustment of the diet and of the doses of insulin was made while the patients attended as out-

patients, and only exceptional cases were taken to the hospital for this purpose. As all unemployed diabetics of this district, when requiring in-patient treatment, had to be sent to the hospital connected with the clinic, we were able to conclude accurately that the frequency of hospital treatment decreased among these patients. Again, as most patients were able to prepare the diet at home, the food supply of the hospital kitchen was necessary only in a few cases.

Collaboration with the practitioners proved to be both practical and effective, as the clinic worked exclusively on a consulting basis. Thus they considered the clinic as a welcome help, and practitioners from other districts also sent us cases. As regards the financial side, the additional allowance for extra diet distributed monthly was 10 marks in about 25 per cent. of the patients, 15 marks in about 35 per cent., and 20 marks in about 40 per cent. A few cases which did not require an expensive diet had no extra allowance granted to them. It may be added that we had intended to issue to all our patients a booklet containing, apart from personal data (name, age, address, occupation, membership of any panel or insurance organization), the patient's medical history and any important clinical particulars.

Summary

The organization of, and experiences with, a special clinic for diabetics are described. By suitable and regular supervision metabolic relapses were avoided, and, in general, the patients remained in a good condition permanently. For organizations having a large number of diabetics under their care such consulting clinics are practicable. Also, a considerable saving may be made by lessening in-patient treatment through the constant adjustment of both the diet and the dosage of insulin, and by buying insulin in large quantities at wholesale prices. In this last way alone the consulting clinic on which this report is based saved several hundred marks monthly.

It was proposed to issue a form for diabetics which would describe briefly the condition of the patient for the use of any physician in case of emergency.

I am greatly indebted to Dr. W. Susman for his assistance in translating this paper.

A NOTE ON THE ANAEMIAS OF PREGNANCY

BY

G. D. KERSLEY, M.D.CANTAB., M.R.C.P.LOND.

ASSISTANT PHYSICIAN, ROYAL UNITED HOSPITAL, BATH
AND

D. A. MITCHELL, M.D., F.R.C.S.ED., M.C.O.G.

GYNAECOLOGIST, ROYAL UNITED HOSPITAL, BATH

Much has been learnt during the last few years about both pernicious anaemia and the simple achlorhydric microcytic anaemias described by Witts, but, although Whitby, in 1932, wrote a paper on "Anaemias in Pregnancy," the practical importance of these anaemias has been insufficiently realized. The reason for this is not far to seek, because the onset is so insidious and the symptoms are usually ascribed to the pregnancy. The result is that a really dangerous degree of anaemia, most frequently of the microcytic type, arises without its presence being even suspected, and if such a case comes untreated into labour the danger of obstetric shock, even in the absence of any blood loss, is very great.

Some slight diminution in the haemoglobin content and red cell count of the blood is physiological during pregnancy on account of hydraemia, but in addition to this there is very often a superadded true anaemia. The common anaemias of pregnancy are the simple types which may occur apart from pregnancy, but their onset is masked and their gravity accentuated by the drain of the foetus on the maternal organism, particularly in the latter third of gestation. They may thus be subdivided into five kinds: the common microcytic type, the more rare megalocytic or pernicious type, anaemia due to haemorrhage, anaemia due to haemolysis following sepsis, and lastly the rare acute idiopathic haemolytic anaemia of pregnancy.

Microcytic Anaemias

The microcytic anaemias arise from a break in the erythron, or chain of red cell development, at the level of the normoblast owing to lack of iron. This may be due to one or more of three factors—deficiency of iron in the food, deficient absorption, and excessive utilization. Deficient absorption is mainly due to the observed fact that throughout pregnancy there is a reduction of the secretions of the stomach, including the hydrochloric acid content. Strauss and Castle found that in 75 per cent. of cases there was hypochlorhydria during pregnancy with immediate recovery in the puerperium. The remaining 25 per cent., with normal stomach contents in pregnancy, showed a puerperal hyperchlorhydria. The effect of excessive utilization is seen in the last three months of pregnancy, when the red cell count falls rapidly owing to the fact that two-thirds of the iron make-up of the foetus is then supplied. The blood count is typical of the microcytic form of anaemia described by Witts, in that the haemoglobin is diminished out of proportion to the red cell count, giving a low colour index, and in the absence of signs of haemolysis or rapid blood regeneration. Dyspepsia, dysphagia, soreness of the tongue, and enlargement of the spleen are all sometimes present.

The Rarer Types

The megalocytic type of anaemia of pregnancy is less common and appears to be due, as in true pernicious anaemia, to a break in the erythron at the level of the megaloblast. It differs from the latter only in the fact that achlorhydria is not a necessary accompaniment, and that the condition arises during pregnancy and is spontaneously relieved by parturition. The blood picture

shows the usual high colour index and leucopenia, and cases generally react well to liver so long as neglect of treatment has not allowed them to fall into an aplastic phase.

There is no need to discuss here anaemia due to haemorrhage or haemolysis following haemolytic streptococcal or anaerobic infections, but a word may usefully be said about the acute idiopathic haemolytic anaemias, which are less rare during pregnancy but are probably related to the infrequently seen haemolytic anaemias occurring during other phases of life.

The symptoms of dyspnoea, oedema, syncope, transient amaurosis or paralysis, fever, haemorrhages, etc., are of sudden onset, usually becoming manifest in the latter two months of pregnancy, and are unaccompanied by any signs of infection or toxæmia. They may occur in primiparae or multiparae, they tend to recur in subsequent pregnancies, and the mortality is in the region of 30 per cent. The blood picture usually shows a megalocytic anaemia with active blood regeneration as evidenced by leucocytosis, and the presence of nucleated red cells and polychromasia. There is excessive haemolysis, causing a positive van den Bergh reaction, and the fragility of the red cells is temporarily increased. Examination of the gastric contents may show no abnormality, but the liver and spleen are sometimes enlarged. The cause of the anaemia is unknown, and treatment consists of blood transfusion, and, if the patient's condition warrants it, immediate induction of labour or Caesarean section. Liver treatment also seems to be of value in some cases.

Recognition and Treatment of Microcytic Anaemia

Although for the sake of completeness it has been necessary to mention the rarer types of anaemia of pregnancy it is the common microcytic type whose importance and frequency it is most necessary to realize. The onset is so insidious and the danger is so real if the patient be allowed to come into labour without previous treatment, that it would seem to make at least a haemoglobin estimation at the seventh month a reasonable routine precaution in ante-natal care. Moreover, the anaemia should be recognized early, as it is in this stage, before there is any tendency to aplasia, that a quick reaction to treatment is to be expected.

The best method of treatment is the administration of iron in large doses or liver, according to the microcytic or macrocytic nature of the anaemia, but the fact must not be lost sight of that both may be needed, and this is particularly obvious in the type of case in which there is originally a high colour index and under treatment with liver the cell count improves and the colour index falls, but the patient does not regain her full quota of red cells. In such a case a little iron will usually complete the recovery. If the patient reacts well to treatment the pregnancy should be allowed to go to term, but if the anaemia shows a tendency to aplasia then termination of the pregnancy must be considered whenever the patient appears to be in a fit condition to stand the shock of labour. In those cases in which severe anaemia is discovered only at term labour should be postponed as long as possible to allow of treatment, and, when it commences, Caesarean section with simultaneous transfusion probably affords the least risk of obstetrical shock.

Four Illustrative Cases

There are two points that it is particularly desired to stress: the frequency of a moderate degree of microcytic anaemia in pregnancy, and the consequent risk of obstetrical shock following delivery if the anaemia is not treated. These points, and also the insidious, occult nature of the anaemia, are well illustrated in the following case reports.

Case 1.—This demonstrated the real risk of obstetric shock in a megalocytic anaemia of pregnancy. Mrs. C., aged 42, a multipara of five, gave a history that for three weeks before her last pregnancy, nine years ago, she had severe vomiting, and that she was very ill for some months afterwards. For five years she apparently had had a recurrent urinary infection. Within a month of again becoming pregnant she began to feel ill and vomited. She was admitted to hospital seven months pregnant in a very serious condition, very pale, and with oedema of the feet and abdomen. The urine contained no albumin, the blood pressure was 130, and the blood urea was 22 mg. per cent. The blood count showed a haemoglobin of 30 per cent., red cells 1,300,000, colour index 1.1, and white count of 6,000. A film showed slight anisocytosis and polychromasia and a few nucleated red cells. The patient was treated with liver extract, iron, and transfusion, but after a week she had but little improved. The urine now contained albumin, and the blood count was unaltered. Two days later the patient came into labour, which was rapid and normal in every way, and gave birth to a live child weighing 4 lb. 10 oz. The total blood loss was estimated at under 10 oz. The patient, however, became very shocked and died four hours later.

Case 2.—Some of the difficulties of diagnosis, even in a very severe grade of anaemia, were shown in this case. Mrs. G., aged 25, a multipara of three, was admitted to hospital, seven months pregnant, for toxæmia of pregnancy. She gave a history that for the past month she had felt tired, had had frequent headaches, and had lately begun to "swell up." On admission there was gross oedema of the legs, abdominal wall, and vulva. She was pale, but the pallor was masked by telangiectases on the cheeks. The blood pressure was 120/80, temperature 99°, pulse 100-110. The urine was of 1020 specific gravity, and contained a trace of albumin. Blood urea was 18 mg. per cent. Blood count: haemoglobin 22 per cent., red cells 2,120,000, colour index 0.5, white cells 8,800. A film showed slight anisocytosis and few nucleated red cells. On treatment with massive doses of iron, within two weeks the patient felt quite well, all oedema had gone, and the haemoglobin was 50 per cent., with a colour index of 0.8. A test meal was performed and showed complete achlorhydria. The patient came into labour and had a normal delivery at term, the blood count then being—haemoglobin 80 per cent., red cells 4,000,000, colour index 1.

Case 3.—A typical case of microcytic anaemia of moderate degree. Mrs. H., aged 29, a one-para, gave a history of vomiting and giddy attacks since seven months pregnant. When seen at the eighth month a blood count showed a haemoglobin of 43 per cent., red cells 4,150,000, colour index 0.5, and white cells 4,600. On iron medication the haemoglobin rose to 55 per cent. during the next month, and three weeks later, after a normal delivery, it had risen to 78 per cent.

Case 4.—Another case of moderate degree of microcytic anaemia. Mrs. T., a multipara of two, was seen when seven and a half months pregnant, complaining of paroxysmal tachycardia. On examination the heart appeared normal and the mucous membranes were slightly pale. A blood count showed a haemoglobin of 68 per cent., red cells 3,860,000, colour index 0.88. On treatment with iron the haemoglobin rapidly rose to 79 per cent., the attacks ceased, and she had a normal delivery at term.

Clinical Memoranda

SUPERIOR MESENTERIC THROMBOSIS

In connexion with an article on the above subject by Mr. R. M. Sargent, published in the *Journal* of July 14th (p. 64), it may be of interest to report a case of spontaneous recovery from a superior mesenteric thrombosis which occurred at the Herefordshire General Hospital under the care of Mr. E. W. Du Buisson, who kindly allows me to report it.

A woman, aged 54, was admitted in November, 1916, with abdominal pain and vomiting—pulse 120. An old right femoral hernia was reduced by taxis, and the patient, relieved, insisted on going home. The next morning she was sent in by her doctor as a possible "reduction en masse" with acute abdominal pain and vomiting. The pulse was now 130. At operation the hernia was found properly reduced. The incision prolonged upwards, however, showed one and a half feet of small intestine near the caecum much dilated and rosy red in colour. There was lymph in the coils and a thrombosis of the mesenteric trunk. The contents were milked down, the hernial sac was removed, and peristalsis noted before the abdomen was closed. She recovered well, though enemata were necessary for some weeks.

B. E. W. STALLARD.

Hereford.

VARICELLA AND HERPES ZOSTER

The cases described below, which would appear to show a clear clinical relation between herpes zoster and varicella, seem worthy of record. The Barbara-Edith Convalescent Home for Children at Blechingley is staffed by a matron and a nurse. There are, in addition, three domestics. Apart from these people and myself, as honorary medical officer, the twelve children, admitted there as convalescents from London hospitals and associations, come into contact with no other persons (except their parents, who are allowed to visit them on one day only in a month), since the home is right in the country and some way from any neighbouring dwelling.

Margaret W., aged 3½ years, was one of a batch of children admitted to the home on May 14th, 1934. She had, on the day of admission, her first crop of herpes zoster, localized to the tenth dorsal segment on the left side. Except for her age, her attack of shingles was in all respects completely typical, and was well developed when she was first seen by me on May 24th, ten days after its beginning.

Betty H., aged 3½ years, was one of the same batch of children admitted on May 14th. On June 6th she developed a few vesicles, suspiciously like early varicella, but had no fever. In the light of the other cases, and because of the subsequent course of her rash, there is no doubt that she had an attack of varicella.

Poppy B., aged 4½ years, was also one of the same batch of children admitted to the home on May 14th. On June 7th—that is, on the twenty-fourth day following that of her admission—she developed a crop of vesicles in all respects like early varicella, and ran a temperature (up to 100° F.) for forty-eight hours. By the third day there was no doubt that she had this disease. Since their admission the above three children had come into contact with no outside persons, except on a visiting day, which happened on June 2nd, and which therefore allowed too short a period of incubation for them to have been infected on that day.

On June 22nd Sadie G., aged 4½ years, was seen with typical first-day varicella. She had no doubt been infected by one of the two preceding cases.

Unless the varicella took at least twenty-four days in incubating, which is exceedingly improbable, there seems little doubt that it must have been communicated from the child suffering from herpes zoster, who was a free contact with all the other inmates of the home.

Blechingley.

DOUGLAS ROBERTSON, B.M., M.R.C.P.

Reviews

DERMATOLOGY

For many years the handbook on *Diseases of the Skin* by the late Sir Malcolm Morris was one of the leading authorities on the subject in the English-speaking world, and its popularity may be estimated from the fact that no fewer than seven editions were needed within a little over twenty years. It was always kept thoroughly abreast of the modern developments of the specialty, and in preparation of the three last editions Sir Malcolm Morris was assisted by Dr. S. Ernest Dore. But the seventh and last edition has now been out of print for some years, and has necessarily fallen out of date. Dr. Dore felt that it should once more be brought abreast of the times, and began to revise it for that purpose. But as the revision progressed it was found that although the original structure and classification might be preserved, so much fresh matter had to be introduced that the book became practically a new one. Hence the volume now before us is the production of the joint authorship of Dr. Dore and of his colleague Dr. JOHN L. FRANKLIN.¹ Curiously enough it is somewhat smaller than the parent work, but it is extraordinarily concise, and contains all the essentials of the subject.

Although, necessarily and properly, greater space has been devoted to the dermatoses which are most frequently met with in clinical work, mention is made of very nearly every pathological change in the skin, however rare it may be. In our opinion it is doubtful whether this completeness is advisable in a book intended for students and practitioners. To some extent it tends to give the uninitiated a distorted view of the subject. The vast bulk of patients, both in hospital clinics and in general practice, suffer from a very limited number of diseases. There are, we believe, about three hundred and fifty skin diseases catalogued in nosological nomenclature. Of these at least two-thirds are so rare that they may well be omitted in a textbook intended for students and general practitioners. They interest the specialist alone, and him only as museum specimens; but when a student finds a considerable portion of a textbook occupied with these conditions which are all blessed with names of extraordinary length, he fancies that in order to deal with the skin troubles of daily life he must be familiar with *acanthosis nigricans* and *purpura telangiectodes*, although in all probability he will never see such a case in his lifetime. Hence he sometimes fights shy of the dermatological department altogether, and loses the opportunity of learning to manage the impetigo and dermatitis cases which will comprise 98 per cent. of the skin patients he will meet with in an ordinary practice. We do not for a moment suggest that the perusal of the present work will have this deplorable effect on the student mind, but possibly it would not have mattered if a few of the rarities had been omitted. It is a thoroughly good book, and the old bottles which have been taken over from its famous predecessor in the shape of structure and pattern turn out to be quite well adapted to contain the new wine of modern dermatology.

The illustrations are plentiful and good (some of them, too, we recognized at once as having been transferred from the parent volume), but the authors have not been seduced by the meretricious charms of coloured plates; those plates which one always expects to be so graphic, but which so often are unsatisfactory! Finally, we may add that the book is of convenient size and moderate price, and deserves to enjoy the same popularity as its forerunner.

¹ *Diseases of the Skin. A Handbook of Dermatology for Practitioners and Students.* By S. Ernest Dore, M.A., M.D., F.R.C.P., and John L. Franklin, M.A., M.D., M.R.C.P. London: Cassell and Co. Ltd. 1934. (Pp. 410; 46 plates. 10s. 6d. net.)

BLOOD TRANSFUSION

A monograph on Blood Transfusion in Medical Practice by Dr. R. LIÈGE² is in two parts, dealing respectively with indications for this procedure and the results to be expected from it, and with its possible dangers. The conditions in which blood transfusion may be indicated are placed in four main categories: blood diseases, hæmorrhage from the alimentary tract, typhoid fever, and a miscellaneous group described as infections and intoxications; it will be understood from this that the adjective "medical" in the title of the book is to be interpreted in its narrower sense, since no reference is made to surgical or obstetrical indications. The possible uses of blood transfusion in a number of conditions in which its value is perhaps not clearly established are stated fairly and with caution; the same attitude animates the section on immuno-transfusion, in which a clear distinction is drawn between three different procedures covered by this term. The dangers of blood transfusion are discussed at almost equal length with its indications, and the number of pages devoted to the accidental transmission of syphilis and malaria is perhaps disproportionately large; the remainder of this section is, of course, concerned chiefly with the effects of transfusing incompatible blood.

Alleged instances of a change in blood group which have been reported are discussed at some length, and the author is inclined to believe that such a change can occur. This most disturbing question is one which evidently calls for the fullest inquiry, although those more sceptically inclined will be content to declare that an inherited character must be a fixed one and to dismiss supposed examples of changed group as due to errors of technique. It is perhaps unfortunate that no emphasis is laid on the paramount importance of a direct test of compatibility; if the serum of all patients likely to require transfusions were obtained and kept available as a routine measure these accidents would not occur. Technique, however, is not dealt with in this book, except that a short section is devoted to the special difficulties of choosing a suitable vein in young children.

To physicians and others interested in the medical uses of transfusion this book affords an opportunity of comparing practice in France with that of this country. That the widespread use of transfusion is of somewhat recent development in Paris appears from the fact that the number of transfusions from donors belonging to an organized service has risen from only 220 as recently as in 1929 to 3,738 in 1932. There is a useful bibliography.

AN INTRODUCTION TO BIOCHEMISTRY

It is a matter of no small difficulty for an author of an introduction to a subject to determine precisely how he shall interpret the word introduction. Shall the book present the facts and interpretations in a manner calculated to attract the interest of the neophyte and stimulate him to proceed to a deeper study, or shall it place before the reader a mass of facts, formulae, and figures which may be readily memorized for examination purposes? There is, of course, a place for each of such works, and under present-day educational conditions the latter kind of book will probably have the wider public, provided it is well written and the facts are put in a pleasantly palatable form. If, in addition, the work is up to date and documented with nice selectivity, it is assured of an enthusiastic reception. Such a book is that of Dr. W. R. FEARON, now before us.³

² *Transfusion du Sang et Immuno-Transfusion en Pathologie Médicale. Indications, Résultats, Accidents.* Par R. Liège. Paris: Masson et Co. 1934. (Pp. 174; 16 figures. 22 fr.)

³ *An Introduction to Biochemistry.* By W. R. Fearon, M.A., Sc.D., M.B., F.R.C. London: William Heinemann (Medical Books) Ltd. 1934. (Pp. 313. 10s. 6d. net.)

Biochemistry is a young science, and the rapid increase in knowledge makes it very difficult to present a compendium of facts which will not, almost before publication, be superseded. The methods which are at our disposal in biochemical work are still crude in most branches, and the lack of some unitary biological theory makes our interpretation of experimental results often appear elementary and unconvincing in the face of the vast complexity of life phenomena.

Dr. Fearon deflects somewhat from the usual practice in works of this kind, in that he pays considerable attention to the inorganic elements, but the mode of presentation of this branch is dull, and not even the besprinkling of the text with quotations from the poets saves it. The sections dealing with the organic compounds of biochemical importance contain a peculiar mixture of what might be called theoretical biochemistry and practical tests. The theoretical discussions, classifications, and formulae are excellently done, but the value of the practical directions seems to us doubtful. This is emphatically not a book for the laboratory, and the biochemical tests, if they had to be included, might well have been done in a series of separate sections or in an appendix. As it is, the student will simply have to copy out these tests should he decide to use the book for laboratory work, and use them separately from the general text. Some peculiar remarks in the book must be noticed. For example, the author sees in the fact that muscle glycogen does not fall in starvation to so great an extent as does liver glycogen, evidence of a difference between "reserve" and "structural" glycogen. What "structural glycogen" is we do not know. Another peculiar statement is that the sympathetic constricts the muscular wall of the intestinal tract.

The chapters dealing with intermediate metabolism, reduction-oxidation systems, and the pyrral pigments are excellent, and contain a mine of valuable condensed information. Taken altogether this is definitely a book to have, and will prove invaluable to the student preparing for the higher examinations, as well as for the teacher who wishes to refresh his memory in fields other than his own.

FRACTURE OF THE NECK OF THE FEMUR

Dr. SVEN JOHANSSON, surgeon-in-chief to the Gothenburg Hospital, has published (in English) a monograph, with 157 illustrations, on *The Operative Treatment of Collum Femoris Fractures*.⁴ In short space he gives a good review of treatment from Royal Whitman's original work up to the present day when he is able to give the results of operation after his own method on fifty cases, and to refer in bulk to another 150 operated by the same method in Sweden by other surgeons. The author is a consistent and rational advocate of osteosynthesis with a stainless steel nail, but, unlike Smith-Petersen, he avoids exposure of the fracture.

There seems good ground on which to base acceptance of Dr. Johansson's conclusions—namely, that by his series of cases he has proved that by proper reposition and fixation osseous union and a fully satisfactory functional result may be obtained in the majority of cases, even in medial collum fractures, and even in very old patients; that it is possible to obtain the fixation necessary for good union by means of extra-articular osteosynthesis on the principle and by the method described in the present volume; that the method, in spite of its wider indications, probably reduces the mortality risk; that osseous union is effected in shorter time, and the after-treatment simplified; that the conservative treatment hitherto used,

as well as operative treatment with exposure of the fracture, should therefore be abandoned and replaced by extra-articular osteosynthesis as the standard method. We must not be taken to suggest that such a method can be placed in the hands of every surgeon. Special experience of orthopaedic measures, as well as of the apparatus employed, is necessary, and every step must be guided and checked by x-ray control. The object must be to provide enough centres to which patients can be brought for early treatment, rather than to attempt to place highly trained and experienced operators in every town.

HYGIENE FOR NURSES

To write briefly and well for nurses, who although not medically trained are so closely in touch with the affairs of medicine, is perhaps not very easy on any medical topic. In the case of hygiene it is especially difficult, since there is on the one hand so much to say because it is important, and on the other so much to omit lest it overweight the reader. In the fifth edition of Dr. WHURRY's handbook⁵ the essentials of the subject are well presented, and little appears that is superfluous, unless it be McKinnel's ventilator, with diagram, which is scarcely worthy of the space it occupies. Particular attention has been paid to infection, food, and personal hygiene. In the chapter on infection, preventive medicine is happily described as a practical large-scale application of the aseptic technique of the operating theatre. Immunity is well summarized, and what is said on the Schick test is sufficiently informative. The part played by milk in spreading typhoid fever nowadays might perhaps have been more emphasized. The advantage of the cresol derivatives in disinfection is properly indicated, but it would, we think, have been of service to lay more stress on the respective values of concurrent and terminal disinfection, since the former, which is mainly the nurse's duty, is now to be regarded as the more important of the two. In the chapter on food the canned tomato is noted as a good source of vitamins. Ptomaine poisoning is described as "of rare occurrence," which is a step in the right direction. In the chapter on personal hygiene an hour's tennis is preferred to stereotyped muscular exercises, which is good advice. The above remarks, where critical, merely reflect shades of difference of opinion. We have found no errors in the book, which is concise and lucid in style, and well adapted for reading by nurses. We commend it to their teachers also, who will find it a reliable guide in deciding not only what to say but how best to say it.

The State examination in hygiene for nurses now covers a field which in scope at least, though the standard of knowledge expected is different, is comparable with that professed by the student of medicine. With a view to helping the nurse to prepare herself for this ordeal the Sister Tutor of Middlesex Hospital has published a guide to the examination in the form of question and answer.⁶ The questions for the written examination appear to be well chosen. A number of them have doubtless already been set and the rest are such as might be. The answers given are of suitable length, and should satisfy the examiners. A useful feature is the inclusion of specimen oral examination questions, the answers to which are not expressly supplied, being contained in the text elsewhere.

⁵ *The Operative Treatment of Collum Femoris Fractures*. By Sven Johansson, M.D. Copenhagen: Levin and Munksgaards. 1934. (Pp. 148; 157 figures.)

Notes on Books

New editions of two large and well-illustrated textbooks of histology have reached us from America. One is a sixth edition* of a work by Dr. HARVEY ERNEST JORDAN, professor of histology and embryology in the University of Virginia; the other is a second edition,* reshaped typographically throughout, of the work by the late Professor ALEXANDER MAXIMOW and Dr. WILLIAM BLOOM, of the University of Chicago.

The *Cranio-cerebrale Schemata für die Roentgenographische Lokalisation*,* by Professor A. SCHÜLLER and Dr. H. URBAN, are intended to help the radiologist in localizing intercerebral disease and in determining the exact situation of foreign bodies. The method is simple, quick, and precise enough for practical purposes. It has none of the disadvantages attached to the various means of localization of intercerebral disease by contrast methods. The authors claim that endocranial foreign bodies—including projectiles and air pockets, abnormal calcification and ossification of the skull (so-called "cerebral stones"), calcified and ossified tumours of the brain, its membranes, and vascular system—can all be accurately localized, as can also traumatic defects. A detailed description is given of the radiographic technique, which is very easy to carry out. The radiologist will find the "Cranio-cerebrale Schemata" a valuable addition to the many methods of localization.

No. 13 of the medical pamphlets issued under the auspices of the Medical Society of Individual Psychology¹⁰ comprises two lectures by Dr. ALFRED ADLER and an address by the late Dr. F. G. CROOKSHANK, together with some miscellaneous matter. These pamphlets are now edited for the society by Dr. J. C. Young.

First Aid in Defence against Chemical Warfare, by Major-General D. J. COLLINS and Major H. STUART BLACKMORE, is a booklet issued by the British Red Cross Society.¹¹ It was first published in 1929, and a second edition has now appeared. The subject is one of considerable topical interest, for reports from the Continent show that great attention is being paid there to methods for protecting civilian populations in cities against aerial gas attacks. The book gives a short and clear account of the chief types of gas used in the Great War, and of the methods that were then elaborated for treating gas casualties. An intensive gas attack on a large city is a horror of which at present we have no experience, but medical men who had much to do with gas casualties in the Great War can visualize some of its probable effects. A chapter is devoted to the protection of the civilian population based on the recommendations of the International Red Cross Committee. The general idea appears to be to organize an ambulance service, adequately protected by masks and clothing, for the collection of casualties and to tell the rest of the population not to give way to panic. It may be appropriate to mention here a paper on "The Chemist and National Defence," which was read by Mr. J. Davidson Pratt before the Glasgow Section of the Society of Chemical Industry on October 5th, and has since appeared in *Chemistry and Industry*.

The 1934 edition of the Register of Members of the Chartered Society of Massage and Medical Gymnastics¹² covers the period July, 1920, to April, 1934. A new section has been made for those who are not practising.

* *A Textbook of Histology*. By Harvey Ernest Jordan, A.M., Ph.D. Sixth edition. London and New York: D. Appleton-Century Company Inc. 1934. (Pp. 738; 610 figures. 30s. net.)

* *A Textbook of Histology*. By Alexander A. Maximow and William Bloom. Second edition. Philadelphia and London: W. B. Saunders Company. 1934. (Pp. 662; 530 figures. 30s. net.)

or whose addresses have proved untraceable. Some inconvenience had been caused in the past by failure to distinguish these. In other respects the new issue resembles its predecessors, there being in addition to the main register of masseuses and masseurs a useful place index, which enables a medical practitioner in any part of the country to discover quickly those who are at work in his neighbourhood. Additional qualifications which are also noted include those for medical gymnastics, medical electricity, and medical hydrology. It may be recalled that these masseuses and masseurs undertake no case except under the direction of a medical practitioner; do not advertise except in recognized medical and nursing papers; and do not sell goods to patients in a professional capacity, nor accept secret commissions on the sale of goods. They merit, therefore, the strong support of the medical profession, which is thus safeguarded against the unregistered and uncontrolled practitioners of massage whose training has been less carefully regulated and whose work is not under supervision.

Preparations and Appliances

KNIFE FOR SUBMUCOUS RESECTION OF SEPTUM

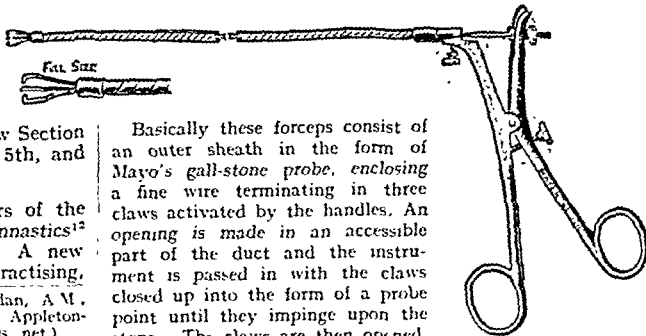

Mr. ARTHUR MILLER, F.R.C.S. (London, W.1), writes: The knife here illustrated has been designed and used by me for the submucous resection of the septum. It is double-edged at the sides and somewhat oval-shaped at its extremity. The incision in the mucosa begins in the uppermost angle of the nostril, and is continued in one sweep right down to the floor of the nose. The lower cutting edge starts the incision; about half-way down the septum the extremity of the knife

takes it up; then the upper cutting edge is engaged; and, finally, the extremity is again used to complete the incision on the floor of the nose. The advantages claimed are: facility of producing the incision with one single sweep right down to the floor of the nose; the impossibility of penetrating the septum; and the fact that it takes the place of a sharp dissector to detach the muco-perichondrium. Mayer and Phelps of 59-61, New Cavendish Street, W., are the makers of the instrument.

CALCULUS FORCEPS

Mr. CONAL CHARLSON, F.R.C.S.Ed., honorary surgeon, Perth Royal Infirmary, writes: The difficulty of removing certain calculi from the bile ducts and ureters has led me to devise the instrument shown in the accompanying illustration.

Basically these forceps consist of an outer sheath in the form of Mayo's gall-stone probe, enclosing a fine wire terminating in three claws activated by the handles. An opening is made in an accessible part of the duct and the instrument is passed in with the claws closed up into the form of a probe point until they impinge upon the stone. The claws are then opened, this action being synchronous with their advancement distally to grip the stone. The grip is tightened and the forceps withdrawn, carrying with them the calculus if all goes well.

The claws open sufficiently to grip strongly anything up to the size of a large pea, and are designed to cause the minimum of trauma to the mucosa of the duct on introduction or withdrawal.

I am indebted to Messrs Mayer and Phelps for carrying out the manufacture of this instrument with considerable skill.

THE OUTLOOK IN NEUROLOGY

"A rare and precious gift," says Osler in one of his essays, "is the Art of Detachment by which a man may so separate himself from a lifelong environment as to take a panoramic view of the conditions under which he has lived and moved: it frees him from Plato's den long enough to see the realities as they are, the shadows as they appear. Could a physician attain to such an art he would find in the state of his profession a theme calling as well for the exercise of the highest faculties of description and imagination as for the deepest philosophic insight." Dr. James Collier's Harveian Oration on "Inventions and the Outlook in Neurology," which we publish to-day, is an outstanding example of this Art of Detachment, and exhibits to the full those powers of description, imagination, and philosophic insight of which he is a master. In his survey of neurology he brings a knowledge of the past to the illumination of the present, and seeks in both for those principles which must guide its future development.

The relationship of form and function in the nervous system is a problem which thrusts itself upon the attention of the neurologist and which most impresses with its difficulty those who have spent their lives in its study. The neurologist, as such, is always concerned with a damaged nervous system. He stands outside it and watches its attempts to carry on its functions in spite of its injury. He is like a geographer trying to draw a map of a country by observing the effect of an earthquake upon the arrival and departure of trains at the railway termini and by questioning the passengers. An injury of the nervous system, whether produced by experiment or by disease, will throw most light upon function in those regions where function is a rudimentary telegraphic conduction of impulses. Hence we know much about the functions of the peripheral nerves and of the spinal cord and practically nothing about the functions of those regions of the cerebral hemispheres which are concerned with thought, speech, and feeling. The conducting functions lend themselves to a high degree of localization, as, for example, in the tracts of the spinal cord. The psychical functions of the cerebral hemispheres are not amenable to localization in the same way. Nevertheless, although the early crude notion of localized centres for speech, sight, and hearing has been abandoned, a sublimated form of it can be found, at least as a working hypothesis in the equipment of many, if not most, neurologists. In part this is because the clinical effects of localized lesions of the

brain indicate that localization of function exists up to a point, though Dr. Collier believes that this is limited to "the input and output paths." In part the persistence of an outworn theory of cerebral localization is due to the difficulty of forming any clear conception of how the brain can function as a whole, and, indeed, of how a network of neurones can function at all to produce thought and feeling out of conducted impulses. To regard, let us say, the Harveian Oration as a manifestation of reflex action, however elaborate, is an act of faith, not a conclusion of science, and owes its plausibility, if plausible it be, to certain philosophical presuppositions. It is unlikely that any progress towards a solution of this problem will be made until it is recognized that form, which is three-dimensional, is incommensurable with function, which, since it involves time, is four-dimensional.

Some of Dr. Collier's views will encounter criticism. Although to him belongs the credit for suggesting that Bell's facial palsy might be due to the virus of herpes zoster, the researches of Drs. R. S. Aitken and R. T. Brain¹ have shown that this is true of less than 20 per cent. of cases. Few neurologists will accept Dr. Collier's contention that in disseminated sclerosis "the process of demyelination," itself symptomless, "is all over and irretrievable so soon as progressive symptoms are present." Nor will it be generally agreed that the recognition of deficiency diseases has made toxic absorption of no importance. The two may be closely related, as is demonstrated by Mellanby's² observation that vitamin A protects the organism against the toxin which causes convulsive ergotism. These, however, are unimportant details. The main implication of Dr. Collier's oration is that a new orientation of neurology is occurring. Applied anatomy and applied physiology, which proved so fruitful a field of research for many years, are becoming exhausted, but the new regions into which neurology must expand are in danger of being claimed by other departments of medicine and of becoming, in Dr. H. A. Riley's³ apt phrase, a "neurologia irredenta." Neurology is being encroached upon by general medicine, by biochemistry, and by bacteriology, as recent developments in the treatment of subacute combined degeneration and of poliomyelitis, for example, illustrate. These encroachments are in the interest neither of the patient nor of medicine as a whole, but they are inevitable unless, as the horizon of neurology becomes extended, the range of vision of the neurologist enlarges proportionately. The view of neurology which Dr. Collier presents is essentially biological. The nervous system can no longer be treated in isolation from the rest of the organism, nor the organism in isolation from its environment. Progress in neurology requires of the neurologist not only readiness to co-operate with workers in many other fields, but also the insight to perceive when such collaboration can be fruitfully undertaken.

NATURE AND TREATMENT OF PERNICIOUS ANAEMIA

Although liver therapy has altered entirely the outlook for cases of pernicious anaemia, speculation and experiment have not yet thrown light upon the essential nature of the disease. It is well that the state of our knowledge should be reviewed from time to time, and the memorandum¹ on the subject recently prepared by Dr. E. W. Adams gives an admirable account of the more important recent researches. Pernicious anaemia is characterized by a distinctive blood picture, achylia, and, in many cases, a combined degeneration of the spinal cord. That it is a deficiency disease is held by many. Castle has formed an interesting theory that there is a lack of a specific intrinsic factor which is present in normal human gastric juice and absent in that of pernicious anaemia. In the normal individual this intrinsic factor of the healthy gastric secretion interacts with an extrinsic factor present in the food to produce specific haemopoietic effects. That the extrinsic factor is allied to vitamin B₁₂ is suggested by the actively curative results of feeding with marmite in some cases. Wilkinson has brought forward evidence that the intrinsic factor is an enzyme-like body which, acting on a substance in the food, produces an active principle, and this active principle can be stored in the liver and stimulates the formation of red blood corpuscles. Since the stomach in pernicious anaemia has none of the intrinsic factor the normal stimulus to blood formation is absent.

Although these theoretical considerations leave much work to be done before a solution is obtained, there is no doubt that a new era in the treatment of pernicious anaemia was inaugurated by the discovery by Minot and Murphy of the efficacy of a diet with abundance of liver and muscle proteins in blood regeneration. This diet contained little fat, plenty of vegetables and fruits, and was especially rich in complete proteins and iron; and observations soon showed that in liver a really effective treatment for this hitherto intractable disease had been found. Further work demonstrated that the effective principle in liver was contained in the non-protein fraction of liver substance, and liver extracts were prepared which appeared to be as efficacious as whole liver and presented certain other advantages. These liver extracts are now prepared in solid and liquid forms, and are designed for both oral and parenteral administration. Patients can take them more easily. They can even be given by the intravenous or intramuscular route, and thus a much more rapid action is obtained by small amounts of material. This rapidity may be essential in the initial treatment of severe cases. While for a time attention was mainly directed to the use of liver and preparations derived from liver, other organs of the body were examined as to their content of

the pernicious anaemia factor. Tests indicated that desiccated stomach tissue is an agent at least as powerful as liver in combating pernicious anaemia; but it is interesting that the stomach of the hog or some other carnivorous animal must be used in making gastric preparations, the herbivorous animals, such as cow and sheep, not being suitable. The effective principle in hog's stomach appears to be less stable towards heat than that obtained from liver, so that in preparation it is not heated above 45° C. Two cases of food poisoning have recently occurred from the administration of stomach tissue preparation, presumably because the degree of heat for drying the preparation is insufficient to kill pathogenic organisms. Beef, calf, fish, chicken, and pork liver are all effective if taken in adequate amounts. It is not necessary to nauseate the patient by giving the liver raw. Since the active principle in liver is fairly stable towards heat, it may be given lightly cooked. The average daily dose of liver may be taken as half a pound, though more may be needed at the outset of treatment. When the blood count reaches normal the quantity may be reduced, and the average maintenance dose is about a quarter of a pound daily. The necessary daily amount may be taken either at once or in divided doses. There is evidence, too, that the response is quantitative, so that a single large dose may yield the same response over a period of days as the same quantity divided into several doses. The effectiveness of the liver principle is more powerful when injected intramuscularly or intravenously; smaller doses may produce the same effect, and much work has been done in preparing extracts suitable for parenteral administration.

Preceding the clinical improvement there is a temporary and often considerable increase in the number of young red blood corpuscles (reticulocytes) in the blood stream after feeding with liver or stomach preparations, and this reticulocyte response is a test of great value in confirming the diagnosis, foreshadowing the improvement, and showing the efficacy of the particular liver or stomach preparation that is being employed. At the present time the only way to test the efficacy of a new batch of liver extract or stomach preparation is by observing the reticulocyte response in a hitherto untreated case of pernicious anaemia. Formerly not all preparations were tested in this way, and some were placed on the market which were useless. Potent extracts, however, have a distinct place in treatment of desperate cases, where there is no time to wait for the slower action of oral ingestion; and some patients prefer the intravenous or intramuscular route to the daily ingestion of liver or stomach preparations. For maintenance, depending upon the particular brand of extract and the nature of the case, the amount necessary for each injection may vary between 2 and 5 c.cm.; and some patients may be kept well on a single injection at intervals of one to six weeks or more. Other measures are beneficial in treatment, but none can be substituted for liver or gastric preparation. Marmite has been found to be as satisfactory as liver

¹ Recent Researches on the Nature and Therapy of Pernicious Anaemia. By E. W. Adams, M.D. Ministry of Health, Reports on Public Health and Medical Subjects, No. 75. H.M. Stationery Office. (ed.)

in the treatment of the tropical macrocytic anaemias, but neither it nor other yeast preparations can replace liver, liver extracts, or stomach preparations in the treatment of pernicious anaemia. Iron is generally regarded as ineffective in this disease, but when certain complications are present the combination of liver and iron may be of great value. Iron is also of use in the presence of sepsis and arteriosclerosis, and in some rare cases in which, during treatment by stomach or liver, the red cell count outstrips the haemoglobin level.

RECENT WORK ON LEPTOSPIROSIS

In Holland Weil's disease has assumed considerable prominence, while the apparent immunity of England has been seriously questioned as a result of Dr. Hamilton Fairley's observations, published in the *Journal* of July 7th, 1934 (p. 10). During the last ten years 452 cases have been recognized in Holland, of which forty-six (10.2 per cent.) proved fatal. The disease, according to Professor Schüffner,¹ is commonest in the western coastal part of the country, and has its maximum incidence in the province of South Holland, where the case rate is 140 per million. The disease may appear in any month of the year, but the commonest time is July to October. During the hot summers of 1932 and 1933 the summer peak was very marked indeed, and was apparently associated with the increase in bathing. Infection may occur in a number of ways. Bathers in infected areas are exposed to serious risk. Persons who fall into canals, by accident or with suicidal intent, provide a number of cases. Bargemen, fishermen, and workers in slaughterhouses and other rat-infested premises contribute more than their due quota. Infection may also arise from dogs. Water becomes infected with *Leptospira icterohaemorrhagiae* from the urine of sewer rats. In Rotterdam, where cases of Weil's disease are fairly common, from 7 to 40 per cent. of all rats examined have been proved to be infected. The frequency depends largely, however, on the age of the rat. In young rats in Rotterdam no infections were found, while in Amsterdam only 3 per cent. of young rats proved positive. Adult rats, on the other hand, are infected up to a figure of 45 or even 60 per cent. The black rat rarely acts as a carrier. The survival of the leptospirae is determined to some extent by the salinity of the water. It was found that in alkaline water with not more than 40 mg. of chlorine per litre, the organisms survived for ten days or longer, in water with 1,700 mg. for three days, and in sea-water, with 17,000 mg., for only a few hours. Clinically, about 60 per cent. of cases show no jaundice. The true nature of the disease in these cases is suggested by the severe muscular pains at the onset, the heavily coated tongue, the albuminuria, meningeal symptoms, the shift to the left in the leucocyte formula, and, probably most striking of all, the flushed conjunctivae due to dilatation of the episcleral capillaries. Cases without jaundice are not fatal. The diagnosis has to be made finally by the bacteriologist. Though leptos-

pirae can almost invariably be found by dark-ground illumination in the freshly drawn blood of infected guinea-pigs, they are rarely found by this method in human cases. They may be sought for, however, by light centrifugation of the blood and examination of a thick layer of the supernatant plasma. Cultivation of the blood is much more successful, either directly or after preliminary passage through the guinea-pig. The organisms are commonest in the blood during the first three or four days, but they may be found as late as the tenth day, especially in severe cases. After that they may be sought for in the urine. The most generally useful method, however, is the agglutination test, which becomes positive as the patient recovers. It is carried out with living, or preferably with 0.2 per cent. formalized, cultures. The most important advantage of using killed organisms is that the reaction is not obscured by the occurrence of lysis in the lower dilutions, thus allowing absorption of agglutinin experiments to be carried out. The main type of leptospira causing Weil's disease in Holland is *L. icterohaemorrhagiae*, but a second type, *L. canicola*, has been found as a cause of infectious jaundice in dogs, and of at least one case of human disease. These two organisms, which differ in virulence for guinea-pigs and in serological behaviour, are both different from *L. grippityphosa*, the infecting agent in the swamp fever of Eastern Europe.

GOLD THERAPY IN PULMONARY TUBERCULOSIS

In the front rank of those attempting to consolidate the position of chrysotherapy by accurately determining indications, dosage, and results must be placed Professor Sayé, whose book¹ elaborates the account he gave at the International Tuberculosis Conference at The Hague in 1932. After mentioning the various gold preparations employed in therapeutics, he summarizes the work of other authors with sanocrysin and then describes his own experience, based on 434 patients treated between 1925 and 1931. Rest formed part of the treatment in 342, 40 per cent. being in hospital and the remainder in their own homes, and ninety-two received the sanocrysin as out-patients. The author maintains that his results are particularly demonstrative, as, owing to the lack of sanatorium accommodation in Barcelona and the poor economic circumstances of the patients, less than 15 per cent. were able to undergo a *cura climática* on completion of the course of sanocrysin. In 131 patients only was some form of collapse therapy also instituted. The results, very satisfactory as a whole, are critically examined from different aspects, but in view of the heterogeneous material dealt with very little would be conveyed by quoting the figures. Rather should the results be studied in the clear and concise notes of the fifty illustrative cases and their accompanying excellently reproduced skiagrams. The indication *par excellence* is the early exudative lesion, whatever its extent, and sanocrysin will produce a complete and lasting cure more rapidly (and more conveniently) than will an artificial pneumothorax, and, moreover, with no residual fibrosis. This *nettoyage radiologique* may be

¹ Schüffner, W.: *Trans. Roy. Soc. Trop. Med. and Hyg.*, 1934, xxviii, 7.

¹ *Crisoterapia de la Tuberculosis*. Por el Dr. Luis Sayé. Barcelona: Salvat Editores, S.A. (34 pesetas unbound, 39 pesetas bound in cloth.)

seen even with large "acute" cavities. Relative indications, with surprising results sometimes, are moderately advanced caseous and ulcerative cases, but here, too, it is chiefly the "infiltration," the "fresh spreading disease" of Gravesen, that is most influenced, often preparing the ground for some form of collapse therapy. Old-standing cases with much fibrosis, profound toxæmia, and severe tuberculous lesions elsewhere are contraindications. It is in regard to dosage that Sayé differs considerably from other authors. While the initial and subsequent doses vary according to the weight and general condition of the patient and the type of disease, in nearly 50 per cent. of the bed cases a dose of 0.8 gram or more is reached; in 40 per cent. the total amount was over 8 grams, and sometimes 20 grams or more. He maintains that such dosage improves and hastens the result, and is rendered possible by regulating the size and interval of doses according to the following principles. Small or single rises of temperature, slight transient albuminuria, and fleeting erythemas must be regarded as focal reactions and the next dose given after disappearance of the symptoms. Gastro-enteritic disturbances, dermatitis, and persistent albuminuria indicate metallic intolerance, and call for an increased interval and a similar or smaller dose. Repetition or multiplicity of intolerance symptoms indicates metallic saturation and compels cessation of treatment. Sayé claims to have reduced the intolerance symptoms to 10 per cent. and rarely to experience saturation syndromes, the appearance of which has also a prognostic value. The importance of the effect on the early exudative lesion—which is in line with the work of Gravesen and Christensen—cannot be overestimated. Routine examination of contacts and the "supposed healthy" is becoming established in America and Germany, and will undoubtedly develop in England. In this way the "early cases" so eagerly clamoured for will be discovered and the problem of dealing with them bound to arise. While Sayé admits the possibility of a spontaneous cure in a number of these, clearly no method is yet available for distinguishing the two types, so that "ambulant" chrysotherapy may offer us the best and most convenient solution. Professor Sayé's book has a lesson to teach, and it is to be hoped that an English translation will soon make its Spanish contents available to English readers.

GEE'S DISEASE

Eponyms are of more historical than everyday value, and therefore often tend to die out when the nature of the disease, the sign, symptom, instrument, or what not becomes more definitely established. Some, however, appear to be permanent exceptions, such as Bright's disease, which has an umbrella-like character, covering a number of physical sins; Graves's disease, which is less committal than exophthalmic goitre; and Addison's disease. Samuel Gee, an outstanding clinical teacher and personality at St. Bartholomew's Hospital in the last quarter of the nineteenth century, is an example of one whose name is now but little known eponymously. It was not ever thus. At one time posterior non-tuberculous meningitis was known as Gee and Barlow's disease, from their description in 1878 of what Still subsequently showed to be a chronic form

of meningococcal meningitis. Gee's linctus was at the beginning of this century widely used for a mixture of equal parts of tinct. camphor. co., syrup of tolu, and oxymel of squill, the origin of which, according to tradition, was that a hospital patient mentioned the superior qualities and the miraculous cure obtained from the medicine given by the village lady bountiful, who on inquiry revealed its composition, and thus insured its further employment at St. Bartholomew's Hospital. A somewhat similar linctus at St. George's Hospital was once familiar as (J. W.) Ogle's drops. These are examples of how great clinicians may be best known on account of their least profound achievements. Addison's, or more correctly Baillie's, pill is another. In 1932 Izod Bennett, Donald Hunter, and Janet Vaughan¹ contributed a monographic and well-illustrated account of "idiopathic steatorrhœa (Gee's disease)," which Gee² described in children as coeliac disease in 1888, and C. A. Herter rediscovered twenty years later. The valuable article in 1932 was based on fifteen adult cases. In September last Izod Bennett³ published, under the sole title *La Maladie de Gee*, a shorter account of this complex metabolic disorder. Thus may be revived abroad, and in a country where Trousseau in the past generously introduced the eponyms "Graves's disease" and "Addison's disease," the memory of a great British physician whose name in this country should be kept green by the collection of "Gee's aphorisms" made by his pupil and follower Lord Horder.

CARBON DIOXIDE FOR THE NEWBORN

The introduction of carbon dioxide in oxygen in a proportion of 5 to 7 per cent. for the treatment of various types of respiratory failure has an obvious application in the newborn, and workers in various centres have not been slow in availing themselves of this method. There are, however, certain details to be observed, which are well set out in a recent article⁴ from Bordeaux by Drs. G. Péry, J. Cardus Llanas, and J. Duffour, the last-named being a "chemical engineer." The first step in the treatment of respiratory failure in the newborn, according to these authors, is to clear the respiratory passages of all obstruction, especially that by mucus. It is pointed out that excessive mucus provides a barrier through which carbon dioxide cannot penetrate, and it is also recognized that the pressures used in the insufflation of the carbon-dioxide-oxygen mixtures may well drive mucus still deeper into the pulmonary tissues unless it is first removed. While this principle is a most important one, it cannot be said that the method advised—nor any of those commonly employed—constitutes the ideal. The authors recommend that the baby be suspended by the feet and the back rubbed to encourage the passage of mucus to the pharynx, from which it is removed by means of a finger wrapped in gauze. Then a special insufflation tube is introduced into the trachea. It is obvious that, as such a measure appears to be necessary, a suction apparatus might well be then applied to extract mucus without such disturbance of the child as is indicated by the

⁴ *Journ. de Méd. de Bordeaux*, April 30th, 1934, p. 315.

manipulations referred to. To the insufflation tube is attached a neat metal device consisting of a tube with a side inlet connected to the supply of carbon dioxide and oxygen. There is a movable inner tube, open to the air and also with a side opening. When this is depressed by the finger or thumb the carbon dioxide mixture flows into the trachea; when released, a spring raises the inner tube and closes the inlet, and expired air escapes through the upper opening, from which the finger or thumb has been withdrawn. The supply of carbon dioxide and oxygen (5 to 7 per cent.) is contained in a rubber bag of five-litre capacity. During the inspiration phase the attendant presses down the metal tube with one hand and with the other squeezes the rubber bag with whatever pressure is deemed necessary for the individual child. During the expiratory phase the hand pressing on the metal tube releases this, while that used for the rubber bag is now transferred to the chest of the infant to compress the thorax. Artificial respiration is continued in this way until a satisfactory cry is produced. It is then recommended that the insufflation tube be removed and further carbon dioxide and oxygen given, by means of a mask if necessary. In the conclusions to the paper the authors also suggest that, if no response is obtained after artificial respiration in the manner described, lumbar puncture should be performed, followed by repeated measures to stimulate breathing. This would appear a drastic way of reducing intracranial pressure which, at such a period in neo-natal life, must be due to a large haemorrhage. The important points brought out by the authors are the absolute necessity of clearing all obstruction from the respiratory tract and the value of positive pressure insufflation into the trachea. The method recorded is certainly an advance towards the ideal when a combined suction and insufflation apparatus can be satisfactorily elaborated.

BILHARZIA DISEASE IN ENGLAND

Dr. J. B. Christopherson and Mr. R. Ogier Ward have lately published a note¹ on bilharzia disease in England, in which they describe the case of a young man who, on his return home to England from South Africa, suffered several attacks of haematuria and pain in the loins. Ova of *Schistosoma haematobium* were discovered in the urine by Dr. Cuthbert Dukes, and the authors give an account, with coloured illustrations, of the cystoscopic appearance of the bladder before and after intravenous injections of sodium antimony tartrate. The patient was kept under observation after treatment, and three years later, when last seen, he was in normal good health, and had been free from all urinary symptoms since the course of antimony. Bilharzia disease, though it not infrequently crops up in England, is always imported. There is on record nowhere a well-established case of the infection having been contracted in the British Isles. Biologically, the authors say, it would not appear impossible for the disease to thrive and to pass from one person to another in this country. "There are stretches of fresh water—for example, at Frensham and Fleet in Surrey, and in other localities—where soldiers bathe whilst at home from abroad in water which harbours species of snails which,

given the opportunity, might function as the necessary intermediate hosts; but there are few days in the year when the miracidium in the ovum would hatch out and survive in the free state and infect the snails. The British climate preserves the country from endemic bilharzia disease."

LET THERE BE LIGHT!

Directors of research laboratories are not commonly noted for powers of vivid expression either in the spoken or in the written word. Dr. Matthew Luckiesh is an exception to this generalization. Since 1915 he has written a series of books on lighting. Some have dealt with the technical aspects of the matter, in others he has sought to bring technical achievements in illumination to the notice of the public. His latest book, *Seeing and Human Welfare*,¹ is a typical piece of propaganda. His theme is the folly, the costliness, and the danger of working or allowing anyone to work in a poor light; and the wisdom, the economy, and the safety of providing a superabundance of light. In a former book his enthusiasm for artificial lighting led him to suggest its superiority over the variable natural light for interior illumination. Here his text might be the splendour of sunlight and the poverty of our common conception of artificial light. The intensity of illumination at midday in summer has been nearly as high as 10,000 foot-candles; even in the shade of a tree it is about 1,000 foot-candles. Daylight indoors is restricted by windows, and its distribution is often unsatisfactory; there may be 200 foot-candles near the window, and only 2 foot-candles ten feet away. A 100-watt lamp may give a light equivalent to 100 candles at a distance of one foot, but the intensity of illumination ten feet from it is about the same as that of one candle at a distance of one foot—a wholly inadequate light for detailed work. Dr. Luckiesh discusses the visibility of objects and the illumination required for various types of work. In all categories he demands standards about twice as high as are commonly accepted; and his standards, he says, are not ideal.

LEWISHAM HOSPITAL

Lord Dawson of Penn asks us to give him an opportunity—and we gladly do so—of amplifying his speech at the opening of the Lewisham Hospital extension on October 9th.² "To praise Dr. Nockolds, the medical superintendent," Lord Dawson says, "is no mere compliment; the Lewisham Hospital owes a large part of its attainments and reputation to his excellent administration. In my reference to the matron I wished to pay tribute to the admirable nursing school at the Lewisham Hospital and the educational reputation it has gained under her direction."

The fifth annual reports of the National Radium Trust and Radium Commission, for the year 1933-4, are published to-day by H.M. Stationery Office (Cmd. 4711. 9d.).

ONE HUNDRED AND THIRD ANNUAL MEETING
of the
British Medical Association
MELBOURNE, 1935

THE British Medical Association will hold its 103rd Annual Meeting in Melbourne, Australia, during the week beginning September 9th, 1935, under the presidency of Sir Richard Stawell, K.B.E., M.D., consulting physician to the Melbourne Hospital. On three occasions—in 1897, 1906, and 1930—the Association has met outside the British Isles, and each time in a Canadian city. The Sectional sessions for scientific and clinical work will be held on Wednesday, Thursday, and Friday, September 11th, 12th, and 13th, the mornings being given up to discussions and the reading of papers, and the afternoons to demonstrations. The Annual Representative Meeting for the transaction of medico-political business will take place in London at the Association's House on Friday, July 19th, and following days.

Members travelling to Australia through the United States will sail for New York from Southampton on Saturday, July 27th; if travelling by the Canadian route to San Francisco, they will sail for Montreal from Liverpool on July 26th, or from Glasgow on July 27th. Particulars of the two routes were given in our *Supplement* of March 10th. All arrangements in connexion with the journey are in the hands of the Financial Secretary and Business Manager, B.M.A. House, Tavistock Square, London, W.C.1, to whom early application should be made for further details, and for reservation of places on steamers and trains and at hotels. Members who cannot afford to be away for the whole time of the "round-the-world" tour, but who wish to attend the meeting, may leave London on August 8th, travelling overland to Toulon and embarking there on a P. & O. liner which arrives at Fremantle on September 3rd. The journey on to Melbourne takes three days by rail, so that those who follow this route will reach their destination on September 6th, three days before the meeting opens. On the social side those responsible for organizing the Melbourne programme are making every effort to ensure that the event shall be worthy of the occasion, and a very warm welcome may be counted on from our Australian colleagues. During the outward and homeward journeys the official B.M.A. party from the British Isles hopes to establish personal contact with many other Branches of the Association.

The honorary local general secretary for next year's Annual Meeting is Dr. J. P. Major, Medical Society Hall, East Melbourne, Victoria. The names of the Presidents of the fourteen Scientific Sections were given in the *Supplement* of August 25th; and the full list of officers, with provisional programmes, etc., will appear in subsequent issues. We publish below the first of a series of descriptive and historical articles on the city of Melbourne and its medical institutions.

A HISTORICAL SKETCH OF THE CITY OF MELBOURNE

For forty-five years after the first settlement of Australia the fertile region which is now the State of Victoria remained practically unoccupied. Twice had an official outpost been established on its shores, only to be withdrawn again after a short period; and once, in 1824-5, an exploratory journey from the outlying settlements of New South Wales had revealed the country lying back from the coast as well fitted to carry the flocks and herds which were becoming the principal pre-occupation of enterprising settlers. From the island colony of Tasmania, where accessible sheep-lands were limited, longing eyes were being cast on the virgin pastures just across the straits; and at length, in November, 1834, the ice was broken by a bold adventurer, who planted himself on the shores of Portland Bay. A few months later several Tasmanian colonists visited Port Phillip to view the country, and in September, 1835, two rival parties, organized respectively by John Batman and John Pascoe Fawkner, camped side by side on the banks of the Yarra River at the head of Port Phillip Bay. From this encampment sprang up a small straggling village of turf huts and one or two weatherboard houses, which was the progenitor of the city of Melbourne.

It was the policy of the British Government at that time to discourage the dispersion of settlers beyond certain defined limits in New South Wales, and in duty bound the Governor of the Colony issued a notice warning off the intruders from the south. At the same time he wrote to the home authorities pointing out the impossibility of restraining the spread of pastoral occupation, and suggesting that he should be authorized to bring the new-

comers under official control by establishing a regular township on the southern coast. This suggestion was adopted, and in September, 1836, twelve months after that first encampment at Port Phillip, Sir Richard Bourke sent a police magistrate thither to take charge of affairs.

In March, 1837, the Governor himself journeyed south to decide upon the site of the new town. "I found on my arrival on the spot selected for a settlement . . . on the banks of the Yarra River," he reported to the Secretary of State, "an assembled population consisting of from sixty to seventy families. The situation appearing to be well chosen, I directed a town to be immediately laid out, which your Lordship will perceive from the map has received the name of Melbourne." Streets were pegged out without regard to existing habitations, and on June 1st, 1837, the first sale of building allotments was held. With the country round about it filling up with pastoralists from Tasmania and also from the older settlements of New South Wales, the new town made at first phenomenal progress. By the end of 1839 it must have had a population of something like 3,000, and in 1842 it was deemed of sufficient importance to be incorporated and to have a mayor and town council.

Notwithstanding the wave of financial depression which followed the "boom" of the early 'forties, Melbourne had by 1845 acquired several respectable places of worship, a theatre, and one or two substantial Government buildings. The official census of the following year showed a population of 10,000; and in 1848 the town was made the see of the bishop and raised to the dignity of a city.

Victoria Becomes an Independent Colony

After several years of agitation the Port Phillip district was separated from New South Wales, and became the independent Colony of Victoria in 1851. Following hard on this event came the discovery of rich goldfields within

built, and extensive Government buildings, including stately Houses of Parliament, were begun.

By 1861 Melbourne and its suburbs, most of which now had municipal councils of their own, housed 140,000 people. The older city of Sydney was left far behind,

EARLY VIEW OF COLLINS STREET.

COLLINS STREET IN THE 'SEVENTIES

its boundaries and a rush of immigration, mainly from Great Britain, to the new Eldorado. From 1852 to 1854 the average number of oversea arrivals in Victoria was 90,000 per annum. Although Melbourne was now a city with 20,000 inhabitants, it could not cope for long with the demands made for accommodation by this horde of gold seekers. The result was the growth of a large camp on the waste lands to the south of the river, which at one time held nearly 5,000 people. "Canvas Town," as it was called, was under the control of the Crown Lands Commissioner, and was laid out in regular streets and lanes; but it was only a temporary expedient, and by 1854 it had begun to dwindle out of existence. Things were settling down, and the huge access of population was making itself felt by causing rapid suburban expansion and stimulating social developments generally.

The "Land Boom" and Its Effect on Melbourne

Between 1854 and 1859 Melbourne held its first exhibition, in a miniature "Crystal Palace" hastily erected in William Street. A suburban railway system was inaugurated, and a university and a public library were founded; a water-supply and gasworks were established; footpaths were paved and roadways macadamized; a volunteer fire brigade system was developed; the first town hall was erected—a remarkable record for a city little more than twenty years old. Three large theatres were also

and for a full forty years Melbourne was the leading centre of population. The 'sixties and 'seventies was a period of steady progress, with the growth of buildings, especially of churches, of an increasing dignity, but without

any spectacular developments. The great International Exhibition of 1880-1, however, ushered in an era of striking changes, surpassing even those of the "gold rush" period. Between 1881 and 1891 the population of Melbourne increased from 282,000 to 490,000. Capital was pouring into the country for investment, and speculation in land was feverish and extravagant. It was indeed a time of artificial prosperity, known to later generations as the "land boom"; but its permanent effects on the city were remarkable. From a fair-sized provincial town it was transformed into a modern metropolis. Buildings eight and nine stories high sprang up as if by magic. A cable tramway system was constructed, and electric light and telephones were introduced. The course of the river was widened and straightened, eliminating the danger of floods, which had been a recurring trouble in the past, and new and

COLLINS STREET, MELBOURNE, 1924.

handsome bridges were erected to connect the northern and southern portions of the metropolitan area. A Melbourne Metropolitan Board of Works was constituted, and the installation of a modern sewerage system was begun.

The "boom" was followed by a severe depression, fortunately mainly local and therefore temporary. In a few years there were signs of recovery, and with the inauguration of the Commonwealth in 1901 Melbourne again came into prominence as the temporary seat of the Federal Parliament, which met there for over a quarter of a century, pending the building of the Federal capital. In 1903 electric tramways were introduced, which have gradually replaced nearly the whole of the older cable ones, and between 1918 and 1925 the entire suburban railway system was electrified, providing a passenger service well able to stand comparison with that of any city in the Old World.

The Modern City

Greater Melbourne of to-day covers an area of 200 square miles, and includes some twenty-seven or twenty-eight independent cities, with a total population of nearly a million. It has 146 miles of tramways, and its parks and gardens have an area of over 8,000 acres. The latter include the beautiful Botanical Gardens, situated on the banks of the Yarra close to the city, and the Treasury and Fitzroy Gardens, which are on the confines of the business centre. A broad, leafy boulevard, the St. Kilda

Road, leads southward from the Prince's Bridge, adorned by numerous statues and monuments, and its vista closed in by the great War Memorial Shrine erected between 1928 and 1932. At the entrance to the city stands St. Paul's Cathedral, erected nearly fifty years ago, but its graceful spires only recently completed. The Town Hall and Elizabeth Street Post Office are both buildings worthy of a great metropolis, and the Public Library has a reading room similar in construction to that of the British Museum, but much loftier. The same building houses the National Gallery, one of the most richly endowed galleries of the British Empire.

At the east end of the city stand the Houses of Parliament and the principal Government offices, besides Melbourne's second cathedral, St. Patrick's. To the north lies the University, occupying, with its affiliated colleges, over 100 acres of ground, and attended by some 3,000 students. Beyond the spreading miles of suburban streets, one can glimpse a distant view of surrounding hills, and it is among these that the people of Melbourne build the week-end homes to which they retreat in the summer season; while southwards, along the eastern shores of Port Phillip Bay, stretches a long line of watering places equally favoured in the holiday season.

A. W. GREIG.

HEALTH AND HUMAN PROGRESS

A MEDICO-SOCIOLOGICAL SURVEY

*L'Economie Humaine par la Médecine Sociale*¹ by Dr. René Sand is a really remarkable book. The writer of this notice has had occasion to read, and to be grateful to, many books on medical sociology, but this book is in a class by itself. The previous work of Dr. Sand had made it clear that anything coming from him on a subject he has made his own was to be received with respect and gratitude, but into this particular volume he has poured all his great knowledge and his gift for attractive presentation in such measure that it may be regarded as the complete guide to all interested in citizenship and not least to the medical profession; and it is not only a guide, but an inspiration. M. Herriot, in a preface, says that Dr. Sand's programme may be summarized as a "demand that we make use of progress instead of being subjected by it." The thesis of the book is that human life could be so much richer for all than it is now if we would take the trouble to make it so; that much progress has been made but that much still remains to be done; and that medicine in its widest sense has been a very great factor in human progress and will be even more important in the future.

The difficulty about a book so rich in material is to select. Every chapter might well form the subject of an article. Dr. Sand sees in the widely spread reduction of the birth rate something which is forcing the politicians of the world to realize that preventable sickness and premature death are an intolerable waste of human material, and that social medicine is a factor in human economy which must be encouraged and organized far more than it has been. He shows with a wealth of illustration that "we can buy human life, and every country fixes for itself, within certain limits, its own death rate." He defines social medicine as the art of prevention and cure considered as "something which links the health of men to their condition as human beings." He classifies the elements of the populations of various countries according to their financial resources, and arrives at what he calls a balance sheet of sickness and death. He points out that the increase in deaths in certain categories is a sign of progress when the deaths occur at the more advanced ages.

¹ *L'Economie Humaine par la Médecine Sociale*. By René Sand. Preface by M. Edouard Herriot. Paris: Les Editions Rieder. 1934. (39 fr.)

In an interesting survey of the causes of death (in which great appreciation is shown of the returns of our Registrar-General) Dr. Sand shows that, after tuberculosis, the most frequent cause of death in young women is child-birth, and he suggests that the stationary or even increasing maternal mortality rate is probably due to the results of abortion, though he admits that it is difficult to secure figures to prove this. According to confidential medical reports received from certain German towns the number of abortions there exceeds that of accouchements. Contrary to what might have been expected, at any rate in this country and in New Zealand the deaths from external causes have not increased in spite of mechanization and the motor car, nor is urbanization tending to increase the death rate, the infantile rate in the towns in many countries being lower than that of the rural areas, though in the later ages the country has an advantage. In these matters as in all others the author's conclusions are supported by figures and illustrations taken from all countries.

HEALTH AND INCOME

On the financial cost of sickness he is very illuminating, and his discussion in Chapter V of the argument that the effects of natural selection are paralysed by hygienic measures is worth serious consideration. He is convinced that health depends mainly on income, and he goes into much detail regarding the physical differences at different ages of the various classes of population. His examinations in Chapter VI of "The Inequality of the Classes in Respect to Sickness and Death" and in Chapter VII of "Heredity and Environment," lead him to the conclusion that, "in general, heredity and selection are not the dominating factors in the biological inequalities ascertained as between the several classes." He discusses very fully the theories of the Karl Pearson school, and gives his reasons for dissenting from them.

There is a typically interesting footnote in Chapter VIII on "Heredity Factors," in which he says that the now widely spread opinion that unions between groups ethnically different (Nordic, Mediterranean, Alpine, etc.) are unfavourable from the hereditary point of view is not proved. "Each ethnical group has its own 'hereditary patrimony' which in total is different, but it has not been proved that any one of these patrimonies is in total superior from the biological point of view, and, besides, very few, if any, nations have a homogeneous ethnical population. The Jews were already a composite nation before

their dispersal." He estimates that the population of the world has quadrupled since the eighteenth century and doubled in the nineteenth, and gives figures showing the countries in which the population is increasing, stationary, or decreasing.

On the question of contraception he points out that in Holland, where for thirty years the teaching of contraceptive methods has been legalized and encouraged, the birth rate is 20 per cent. higher than in Belgium, where such teaching is prohibited, and suggests that from the point of view of morals Holland has no reason to fear comparison with its neighbour. Dr. Sand gives much information as to the various suggestions put into practice from the eugenic point of view, and is against family allowances, premiums for births, and assistance to large families, on the ground that these methods encourage the inferior as much as the superior.

Chapter X, on "Professional Factors," gives a full résumé of the rates of mortality in different callings, and figures relating to morbidity, where such are available. There is an interesting discussion whether the higher mortality rate of women workers is due to sex or to the economic factor which compels married women to work. The Baltimore inquiry, which he frequently quotes, showed that even in comparable economic groups the fact that a mother worked away from home had a detrimental effect on the health of the children, but he sees no reason why this need be so, given proper organization.

MEDICINE AND INDUSTRY

The section on the connexion of medicine with industry is very full, and the author points out that this is no new thing, for so far back as 1575 a book on this subject was published by a Spanish physician, Juan Huarte, which had no fewer than twenty-five Spanish and thirty-six other editions. After an acute analysis of the evils caused by industrialism to the individual and the family Dr. Sand concludes that it could easily be turned to the physical, mental, and moral advantage of those concerned, and he gives examples. He is convinced that the slum and unemployment are the two main barriers to the progress of human society. He emphasizes the necessity of promoting the dignity of labour, and points out that in New Zealand, which has done most in this direction, there is not only a lower death and sickness rate than in any other country, but less discontent. Dealing at considerable length with the housing question he concludes that a workman should not be obliged to pay more than one-sixth of the family income in rent.

In his later chapters he further emphasizes his doctrine that all our material existence is conditioned by income, which not only affects health and comfort but intellectual life and morality. Poverty is the enemy. In the long run the community pays for the deficiencies of the employer. Wages inferior to human needs cannot be justified, and, whereas up to the middle of the nineteenth century "neither the peasant nor the townworker could be assured of his daily bread, to-day whole nations are now so rich that all could be properly nourished, housed, clothed, and educated."

SOCIAL INSURANCE AND THE HEALTH SERVICES

He is strongly in favour of social insurance as a preventive of poverty, but believes that the ideal system is one which gives the insured person an interest in not making claims, so that he can make use of money which has been saved by his self-denial for other purposes. Discussing the part played by public and private effort he believes in both, but decides that the major role must be undertaken by the community. The example of the United States of America shows that private effort, however generously supported, cannot take the place of social insurance.

In Chapters XII, XIII, and XIV Dr. Sand makes many suggestions for further advances. He deprecates the waste of effort involved in the multiplication of agencies very imperfectly co-ordinated. He favours health centres, and

alludes to the proposals of Lord Dawson's Committee and the experiment of Drs. Scott-Williamson and Pearse, but thinks it is wasteful to dissociate preventive and curative medicine. The hospital should be the centre for all health work, and he urges the medical profession in this matter to be not only preventive and curative but constructive. Education, though invaluable, will not deliver the individual from his prejudices and weakness, as is shown by the "unpardonable hygienic misconduct of even the best-educated people." The teaching of hygiene in schools is absent in many countries and very imperfectly developed in all. "One becomes an engineer or an officer without having any conception of the role of hygiene in the workshop or the regiment; one founds a home knowing little or nothing of domestic hygiene or how to bring up children."

The book of 285 pages, with a bibliography and list of authors cited, ends in a chapter of sound reasoning and sober eloquence in which an optimistic note is struck, in spite of the sentence in which the author declares: "There are whole continents in which people live under the weight of poverty and disease; for many human beings life is still narrow and sordid; technique serves but dominates us; work is deprived of its joy; thirty million unemployed denounce the incapacity of their rulers; and the spectre of war is not yet laid. Is our task impossible or merely unfinished?" Dr. Sand leaves us in no doubt that in his opinion, given the necessary vision, good will, and organized capacity, the liberation of the world will go on, and that in the future as in the past the medical profession will play a great part, though it must realize far more than it does now the necessity for co-operation with other agencies.

The figures and examples given by Dr. Sand come from nearly all countries, but it is gratifying to find that the author frequently has reason to quote British practice, and his acknowledgements of Sir George Newman's work are frequent and handsome.

We have necessarily given a cursory view of a great book, full of information, practical suggestion, and inspiration. It calls urgently for an English translation, which should be brought to the notice of all who are interested in the important problems it discusses.

Researches conducted during 1933 at the South African Institute for Medical Research included the testing of the potency of concentrated anti-plague serum; this was found to correspond almost exactly with the degree of concentration, thus indicating that concentration up to four times the strength could be achieved. It is stated also, in the annual report of the Institute, that prophylactic pneumonia vaccine for native miners has continued to prove highly satisfactory. A publication embodying the results of the extensive experimental and other work performed in this connexion will be issued shortly. Studies of pneumonia on the Witwatersrand prove that in the native, at any rate, a pneumococcus of the heterogeneous Group IV can be responsible for acute respiratory conditions. All the meningococci recovered from patients during the year proved to be aberrant strains, showing no correspondence with agglutinating meningococcal sera of the recognized local or overseas groups. Rabies infection is assuming more serious proportions in South Africa, and now threatens households through the cat, the tame mercat, and, occasionally, the dog. It has been shown that the rabies vaccine used locally has some value in protecting rabbits against a fatal dose of South African rabies street virus. Attempts to secure early diagnosis of cancer, by various serological methods, proved unsuccessful. An inquiry into the causes of malnutrition has been inaugurated on a broad basis. Data are being collected as regards the heights and weights of children and young adults, and also on the lines recommended by the American Children's Health Association, which are based on comparison of the relations between height, chest width and depth, hip width, and arm circumference—discarding weight as being fallacious. This will pave the way for subsequent study to be undertaken of the values of various foods.

MOTOR CARS FOR 1935

THE OLYMPIA SHOW

[FROM OUR MOTORING CORRESPONDENT]

(Concluded from page 693)

Coupled with their efficiency for modern conditions of traffic, which render exceptionally high speed almost impossible, the existing economic stringency has resulted in cars of 10 horse-power continuing to form one of the most popular types, and, despite the reduction of 25 per cent. in the annual tax as from January 1st next, it would seem that manufacturers are anticipating a continuance of "Ten" popularity, inasmuch as such cars are now being built by no fewer than six makers—namely, Austin, Ford, Hillman, Morris, and Standard, with the Singer Company producing both 9- and 11-h.p. vehicles.

A PRICE ANALYSIS

An analysis of car prices tends to indicate that the vehicles most suitable for medical men fall in the £250-£350 category. Even below these figures there is a wide selection of cars which will fully meet the needs of many doctors and give satisfactory service. Thus up to £150 there is a choice of five covered cars—the remodelled Austin Seven, the 8-h.p. and 10-h.p. Fords, the new Morris Eight, and the Standard Nine. Between £150 and £200 there is a selection of nearly fifteen models, ranging from the Austin Ten at £158 to the Wolseley "Hornet" at £198 10s. Again, between £200 and £250 there are no fewer than sixteen different cars, from the Vauxhall Light Six at £205 to the new front-wheel-drive Citroën at £250. Noteworthy cars in the £250-£300 group are the 16- and 20-h.p. Hillmans at £269, and the 16- or 20-h.p. Morris Oxford at £285, all with six-cylinder engines. Finally, between £300 and £350 there are the Lanchester Ten and the B.S.A. Six, both with self-changing gear, and the Vauxhall Big Six.

INCREASING POPULARITY OF COUPÉS

As mentioned last week saloons continue the most popular in motor body designs. A walk round the Exhibition reveals, however, that it is now being closely pressed by the coupé type of vehicle, this being mostly of the foursome variety—that is to say, having accommodation for four people. As, however, this type is what is known as close-coupled, the leg room for the rear passengers is not usually so liberal as in a saloon. Much ingenuity has been shown in the design and construction of coupé drop-heads, which enable the car to be used either entirely or partially open, or completely closed.

In the following notes on the different makes of car on view reference is only made to those which, in design and cost, are likely to appeal to doctors.

ARMSTRONG-SIDDELEY AND AUSTIN

Only detail improvements have been found necessary in the range of Armstrong-Siddeley six-cylinder cars, which are notable for their preselective self-changing gear-box. The popular 12-h.p. saloon has been reduced from £300 to £295, or with special equipment £305, while for those requiring a more powerful car with greater passenger room there is a 15-h.p. saloon at £435 and a new 17-h.p. model at £465. The Austin Company is for the 1935 season retaining its range of cars from the "Seven" to the "Twenty," but with numerous improvements, including synchromesh gears on three of the four speeds, sloping radiator front, and a combined luggage carrier and spare wheel compartment. The popular "Baby" has been largely redesigned, and has been reduced in price, the saloon with fixed head being now listed at £112, or with sliding roof £128. Useful models for doctors' use are the Austin 10-h.p. saloon at £172 10s., or cabriolet at £178; the "Light Twelve-Four" and "Twelve-Six" at £218 and £235 respectively, the last-mentioned being available with either 13.9- or 15.9-h.p. engine at the same price, and the old but modernized 12.8-h.p. four-cylinder car, with five types of saloon body, costing from £275 to £325.

BRITISH SALMON, B.S.A., AND CITROËN CARS

An interesting newcomer is the British Salmon 12/55-h.p. four-cylinder car, which with saloon body is priced at £395. Continuing its distinction of being, with the Lanchester, the lowest-powered vehicle available with the Daimler fluid fly-wheel and preselective change-speed gear, the B.S.A. 10-h.p. car embodies only detail improvements, except that a model with a slightly longer wheel-base has been added. Prices of saloons range from £210 to £245. The chief B.S.A. innovation is the introduction of a 12-h.p. six-cylinder car embodying all the chief features of the "Ten," available in either saloon or fixed-head coupé from £315. Reference was made last week to the new Citroën 12-h.p. four-cylinder car with front-wheel drive and special body work contrived so as to obviate the employment of the usual chassis frame. Although a striking departure from the usual practice, the new vehicle has been subjected to exhaustive tests, and has become very popular in France. As a saloon it is listed at £250. Other Citroën cars of conventional construction and improved in detail include a "Ten" (11.8-h.p.) saloon at £225, a "Light Twelve" at £235, and a "Big Twelve" at £245, all with four-cylinder engines, and a six-cylinder "Light Twenty" at £285.

CROSSLEY, DAIMLER, AND FIAT

Of the four Crossley cars for the coming season the one which attracts attention is the 10-h.p. four-cylinder "Regis," which at £325 now embodies as standard a four-speed preselective self-changing gear-box, as well as detail improvements. The "Bailla" 11-h.p. car of the Fiat Company is continued, but with a slightly longer wheel-base, providing more room in the pillarless four-door saloon. The gear-box now also provides four speeds—two of which are synchromesh—instead of only three. The price is £210. There is also the 15-h.p. "Ardita" four-cylinder saloon, which has been reduced from £375 to £350. The Daimler 15-h.p. six-cylinder car, the price of which remains at £450, while subject to the same tax as hitherto, has been provided with a slightly longer stroke engine; the body work has also been improved in detail.

FORD AND HILLMAN

The 1935 range of Ford cars—not at Olympia, but at their own display at the Royal Albert Hall—is attractive. The Ford "V-8" is probably the cheapest eight-cylinder car on the market. Chief sales during the past year have, however, been of the popular little 8-h.p. four-cylinder car, which is being continued at reduced prices, while to the range has been added a similar car but with 10-h.p. engine, selling as a two-door saloon at only £135 and with four doors at £145. Numerous detail improvements have again been introduced in the popular Hillman "Minx" 10-h.p. cars, the prices of which in saloon form range from £159 to £185, or £225 for a foursome drop-head coupé. The principal innovation is a four-speed gear-box incorporating the synchromesh principle on all speeds. For medical men requiring a more powerful and more roomy car there is a family saloon with either 16-h.p. or 20-h.p. engine at £269, or in *de luxe* form at £295.

HUMBER, JOWETT, AND LANCHESTER

Although the Humber productions consist chiefly of cars of relatively high horse-power, the range includes a 12-h.p. four-cylinder, the price of which, in view of the many detail improvements in both chassis and body work, has been raised from £265 to £285. The gear-box of this car has now synchromesh gears on all four speeds. Despite the fact that the 7-h.p. Jowett continues as the only car having a two-cylinder engine, its reliability and low running costs have secured for it the support of many motorists. The standard sliding-roof saloon, which sells at £160, has been improved in detail, particularly as regards the mounting of the engine to obviate any vibration. There is also the "Kestrel" *de luxe* saloon at £175, in which a controllable free-wheel is provided in connexion with the four-speed gear-box, and a "Curlew" saloon at £185, which, in addition to the free-wheel, has a special centrifugal clutch. The chief innovation in the Lanchester programme is that, while continuing the four-cylinder "Ten," the makers have introduced a new 12-h.p. model on the same chassis but with six-cylinder engine. Both cars are of high-grade construction, and

embody the Daimler fluid fly-wheel and four-speed self-changing gear. Prices of the "Ten" saloons range from £310 to £335, and of the "Twelve" from £365 to £375.

MORRIS, RILEY, AND ROVER

The chief feature of the 1935 Morris programme is the introduction of an entirely new "Eight" four-cylinder car replacing the "Minor" of former years. Mounted on a special box-section frame, the saloon body has comfortable accommodation for four persons, while the fittings and accessories are as comprehensive as those on the larger cars. At £120 for the two-door and £130 for the four-door fixed-head saloons—sliding roofs costing an additional £12 10s.—it is a model that is bound to become very popular. The "Ten-Four" and the "Ten-Six," two noteworthy Morris productions, have only been improved in detail and provided with slightly larger tyres, a similar description applying to the two models hitherto known as the "Cowley," but now styled the "Twelve-Four" and the "Fifteen-Six." The Morris "Oxford," a very popular car with many medical men, is continued with but slight changes at £285 for the fixed-head saloon and £305 for a sliding-head coupé, a choice of either 16- or 20-h.p. engine being also given. A change in the Morris cars which may be briefly mentioned is that the accelerator pedal is now at the right of the brake pedal instead of central as hitherto. A wider choice of external body colours in either single or double tones is also now available. The Riley cars, which are mainly of the sports type, may appeal to many of the younger members of the medical profession. The "Nine" is being continued with detail improvements, and, known as the 14-litre model, there is a new 12-h.p. four-cylinder car with saloons at £335 and £345. For 1935 the Rover Company is producing two four-cylinder cars—10.8 and 11.9 h.p.—with saloons at £248 and £278, and two "Sixes," of 13.8 and 19.8 h.p. Such features as the clutchless gear-change and controlled free-wheel are being retained, while new points of merit include automatic chassis lubrication and the rust-proofing of all exposed metal parts of the chassis.

THE SINGER AND STANDARD CARS

The Singer Company has a very attractive range of cars for the 1935 season, notable, on certain models, for such innovations as the "fluidrive" transmission and independent front-wheel suspension. The "Nine" four-cylinder saloon costs either £162 10s. or £185 in *de luxe* form, and the 11-h.p. car £245 as a saloon or £275 as a drop-head coupé. There are also 14-h.p. and 16-h.p. six-cylinder models with saloons at £259 and £295 respectively. Mechanically, the Standard cars show but little change from last year, but the body work has been brought into line with modern tendencies. At the lower end of the scale is the "Nine," at saloon prices ranging from £145 to £175. Next are the "Ten," of which five types are available from £185 to £245, and the "Twelve" at £219 to £239. In addition to these four-cylinder cars there is a "Sixteen-Six" *de luxe* saloon at £285.

Vauxhall and Wolseley

The Vauxhall Company provided one of the Show surprises by the introduction of a new version of the "Light-Six" car, which has proved very popular during the past year. The chief innovation is the adoption of independent front-wheel or "knee-action" springing, which is claimed to result in much more comfortable riding, especially when travelling over bad roads. Other improvements comprise lower and roomier body work, a built-in luggage boot, and an easy jacking system. Retaining the "no draught" ventilation arrangement and synchronized easy gear-change, this 12-h.p. car is now priced as a standard saloon at £205, or in *de luxe* form with either 12-h.p. or 14-h.p. engine at £225. Another Vauxhall production which is proving very successful is the "Big Six," which, with either a 20-h.p. or 27-h.p. power unit, is priced at £325. The Wolseley Company is continuing its popular "Nine" four-cylinder car, which as a saloon costs £178, and the 12-h.p. six-cylinder "Horriet" at £198 10s. The latter is now fitted with a special preselective three-speed gear-box. New six-cylinder models are seen in a 14-h.p. four-speed saloon at £240 and an 18-h.p. at £340. A Crossley with engine at the rear is not being shown this year, the only

British car of this type being the 10-h.p. Trojan, a feature of which is the employment of a four-cylinder two-stroke power unit. Curiously enough, the only other rear-engined vehicle in the exhibition is located on the adjoining stand of the German Mercedes-Benz Company. This is a 12-h.p. four-cylinder vehicle with the engine, gear-box, and differential mounted as a unit behind the back axle, which latter is carried by two powerful spiral springs in place of the usual semi-elliptics.

TYRES AND CAR SERVICE

The tyre section, while revealing no startling departures, shows that the competition between the different manufacturers is such as to result in even better tyres than ever, as much as regards their non-skidding qualities as their long-wearing life. Once a prolific cause of trouble and worry, the modern tyre, when accorded a modicum of regular attention, especially as regards the maintenance of the recommended air pressure, may be depended upon for many thousands of miles of reliable service. The Avon Company is continuing its duo-tread tyre introduced a year ago, while the British Tyre and Rubber Company (formerly Goodrich) has introduced a tyre incorporating in the construction of the cover what is known as a "golden-ply" impregnated with rubber compound, which is said to be heat-resisting, and consequently ensures freedom from tyre bursts.

Although of interest chiefly to the trade, a visit to the garage and service station equipment section of the exhibition reveals the many noteworthy appliances which are now available for the rapid and efficient carrying out not only of chassis lubrication and tyre inflation, but for such renovation and repair work as cylinder boring, valve grinding, decarbonizing, brake testing and relining, etc., all of which should have their effect in keeping users' car maintenance costs down to the minimum.

ACCESSORIES

The galleries of the Show are always worth a visit, as they usually reveal a number of accessories which add to the comfort, and on this occasion the safety, of motoring. Space prevents any lengthy reference to this section of the exhibition; attention may, however, be drawn to a few of its features, such as the numerous anti-dazzle headlights and devices, radiator muffs for winter use, and the stoves, etc., for keeping the garage warm during the night in very cold weather. To the list of Price's "Zero" radiator glycerin and other anti-freezing preparations for addition to the water in radiators are now added the newcomers Smith's "Bluecol" and the County Chemical Company's "Stop-it-freezing." Each of the above-mentioned firms issues a chart showing the quantity to be added to the radiators of all the principal makes of cars. At the Schrader Company's stand there is shown a little device that should appeal to doctors who have to look after their own cars. All motorists know what a nuisance it is, to test the air pressure of or inflate the tyres, to have to remove the valve caps, two for each tyre. To obviate this time-occupying task the firm mentioned has introduced a device known as the "Dublchek" cap, which fits in place of the usual large and small valve caps. While so constructed as to be unaffected by dust or water, the device enables the pressure to be tested or the tyres inflated by direct application of the tester or pump. The lighting and starting battery is probably the most frequent cause of doctors' motoring troubles, especially in the winter months when engines are more difficult to start, causing a greater drain on the accumulator's charge than can be replaced in ordinary running. To overcome this difficulty the Westinghouse Brake Company has introduced a device known as the "Westric" battery charger, which can be readily fixed in any private garage in which a supply of electricity is available. The only addition to the car, usually to the instrument board, is a special socket supplied with the charger. With the "Westric" all that is necessary to keep the battery in a state of charge is to connect up the lead from the charger to the socket on the car when the latter is put away for the night, and then to switch on the current. Finally, mention may be made

of a simple yet very useful accessory for medical men discovered on the stand of Smith and Sons, and consisting of a small memo pad with pencil, adapted to be clipped to the rim of the steering wheel of a car. Not large enough to interfere with steering, it can be used as a visual reminder of the calls a doctor may have to make on his rounds. The pad is chromium-plated, and so arranged that refills may readily be inserted.

C. J. W.

Scotland

Vital Statistics of Scotland for 1933

The seventy-ninth annual report of the Registrar-General for Scotland, dealing with the year 1933, includes a statistical summary by Dr. Peter L. McKinlay, Superintendent of Statistics. The principal features of the year under review were a birth rate which was the lowest on record, a marriage rate which was the highest recorded during the last ten years, a death rate below the average of recent years, and an infantile mortality rate which was the lowest recorded in this country with the exception of that for the year 1923. There was a great reduction in deaths from measles extending over the whole year, as against an increase in those from scarlet fever, particularly during the winter months. The death rates from bronchitis and pneumonia were below the average of the preceding five years. The mortality from tuberculosis showed a continued improvement, but there was a further increase in the deaths attributed to malignant disease. The estimated population of Scotland at the middle of 1933 was 4,912,000, comprising 2,364,000 males and 2,548,000 females. This represents an increase of 29,000 in the total population since the middle of 1932, and is attributed partly to excess of births over deaths and partly to inward balance of migration. The number of births registered during 1933 was 44,767 males and 41,779 females, a total of 86,546. The highest birth rate recorded was in the year 1876, when it was 35.62 per 1,000 of the population, and this rate has steadily tended downwards, with the exception of the war years, until, in 1933, it reached 17.62 per 1,000. With regard to deaths, the number registered during the year was 64,848, giving a rate of 13.2 per 1,000 of the population. This rate was 0.32 below that for 1932, and 0.45 below the average of the five preceding years. The death rate is now almost one-half of that recorded half a century ago. It shows a direct relation with urbanization, for when the rates are adjusted for differences of age and sex constitution of the population, the large burghs show a rate of 14.21, as compared with 12.7 in the small burghs and 11.86 per 1,000 in the landward areas. In the counties, inclusive of burghs, the highest adjusted death rate was in Lanark with 14.6, and the lowest in Peebles with 9.8. In the large burghs the highest was in Greenock with 16.1, and the lowest in Arbroath with 11.9. In small burghs it ranged from 15.5 in Kilwinning down to 10.7 in Peebles, and in landward districts from 13.3 in Lanark and in Stirling to 9.1 in Peebles. There were five centenarians whose age was verified, all being females. Since the practice was introduced in 1910 of verifying the ages of reputed centenarians 171 instances have been verified out of 331 reported. The principal epidemic diseases were responsible for 4,072 deaths, as compared with 4,235 in 1932, and of these 2,027 were due to influenza, 762 to whooping-cough, 356 to diphtheria, 310 to scarlet fever, and 219 to cerebro-spinal meningitis. Measles, however, was responsible for only thirty-six deaths during the year, or 856 fewer than in the preceding year. Tuberculosis continued to show a reduction, the total deaths from this cause being 3,910, which was the lowest number yet recorded, and the rate 80 per 100,000.

This was in marked contrast to the rate of 382 per 100,000 which prevailed in 1870. Diabetes was responsible for 711 deaths, an increase of 45 as compared with the figure for 1932, and these deaths included 246 males and 465 females. There were 7,320 deaths from malignant disease, giving a rate of 153 per 100,000 of the population, and accounting for 11.6 per cent. of all deaths. These deaths numbered sixty-two more than in the preceding year, but the rate was the same. From other general diseases deaths were as follows: pernicious anaemia, 312; rheumatic fever, 171; chronic forms of rheumatism, 135; diseases of the nervous system, 8,983, of which 6,641 were due to various forms of apoplexy; general paralysis, 122; locomotor ataxia, 69; diseases of the circulatory system, 11,887—or 781 more than in the previous year—of which 10,489 were attributable to heart disease; of the respiratory system (excluding influenza and tuberculosis), 8,763—1,053 fewer than in 1932—of which 7,891 were due to bronchitis and pneumonia; of the digestive system, 3,771 (excluding malignant disease), of which 573 were attributed to gastric and duodenal ulcer; of the genito-urinary system, 2,629, of which 1,908 were due to diseases of the kidney; of pregnancy and childbirth collectively 512, or sixty-four fewer than in the previous year; puerperal sepsis, 212, or thirty-one fewer than in 1932. Deaths due kidney; of pregnancy and childbirth collectively 512, an increase of fourteen on the figure for the previous year, but a decrease of 85 as compared with 747 in 1930. The most important causes of death were: heart disease, malignant tumours, apoplexy, and pneumonia; and of these the first three showed increases as compared with the statistics for 1932. Among infants the most important causes of death were congenital defects, pneumonia, diarrhoea, whooping-cough, and convulsions. With regard to vaccination it is pointed out that before the passing of the Vaccination (Scotland) Act, 1907, by which conscientious objection became a valid reason for avoiding it, over 91 per cent. of the children were successfully vaccinated. Thereafter the numbers declined, except that in the year 1920, when there was an outbreak of small-pox in Glasgow, the rate rose to 71 per cent., but following this there was a steady decline, reaching in the year under review the lowest record of 49 per cent.

Psychiatry in Edinburgh

The annual report for 1933 of the Royal Edinburgh Hospital, Morningside, is the one hundred and twenty-first of this institution, and the first to be issued by Professor D. K. Henderson as physician-superintendent. His survey indicates that preventive and remedial measures have replaced the old-time custodial outlook, and he gives ample evidence for his statement that certification itself merely ensures continued treatment, whereby the patient is afforded a better chance of recovery than if he were ordering his own destiny. The large number of patients utilizing the out-patient departments, the nursing homes, the Jordanburn Hospital, and applying voluntarily for treatment in West House or Craig House, proves that the treatment of certain forms of nervous and mental disease can be conducted well on a co-operative basis. The psychological clinic under the direction of Professor Drever was established to study behaviour disorders in children, and to give advice regarding educational and vocational guidance. It is more specialized than the other departments, but its purpose of dealing essentially with children during the formative years of their development is of great importance. The clinics at the Royal Infirmary and the Jordanburn Hospital deal with the more medical aspects of psychiatry, whether applied to children or adults. Professor Henderson remarks that the association with the Royal Infirmary is particularly valuable, since it estab-

lishes a relation between psychiatry and general medicine which needs to be more firmly cemented. He considers that the chief benefit of out-patient departments for nervous and mental patients is the opportunity of seeing cases in their incipency, without the patients having to incur the stigma of attending a mental hospital. The out-patient departments, he adds, have familiarized medical practitioners and the public with the fact that many forms of nervous and mental disease are remediable, provided proper treatment is applied at the right time. Such departments are thus valuable outposts in the department of mental health, and safeguard the patient from contracting more flagrant and serious disorders. If more prolonged, continuous, or intensive therapy is required, this is available at the Jordanburn Hospital, or at one of the associated nursing homes, without the utilization of legal formalities. Illustrative cases are recorded in the report, showing how conditions of various aetiology can now be selected for appropriate treatment. With these preventive agencies is combined the treatment of more advanced and less hopeful cases, and occupational therapy is singled out as a method which has proved very valuable. Heredity is no longer regarded from a fatalistic viewpoint, but rather as something which can be modified and helped. Professor Henderson regrets that the medical profession and the public are still too complaisant regarding the huge social, economic, family, and racial burden which mental illness and defect entail. He condemns the German policy of sterilizing the socially inefficient as too drastic, of doubtful practicability, and much too far in advance of public opinion and scientific knowledge. Sterilization in certain individual cases can be used as a therapeutic rather than as a eugenic measure, but it is still too early to adopt it as a uniform procedure for groups of cases which may differ widely in causation. He considers deep psycho-analytic therapy of use in certain specialized cases, but in others the more tolerant elastic methods of a more eclectic school seem to him to offer greater possibilities. There are many obscure biochemical, toxic, and histopathological problems which require investigation and may shed more light in time on the cure of mental illness.

Glasgow Post-Graduate Courses

The winter session of the Glasgow Post-Graduate Medical Association opens next month. Special lectures will be given at the Royal Faculty of Physicians and Surgeons' Hall dealing with practical problems of medicine in the light of recent observations and research. The series of lectures starts on November 27th, when Dr. John M. Cowan will discuss the prognosis of chronic heart disease. They will be open free to all medical practitioners. A series of weekly demonstrations for practitioners on Wednesday afternoons will commence at the Royal Infirmary on November 7th, when Professor A. W. Harrington will deal with coronary thrombosis. The demonstrations, which will cover a wide range of subjects, have been arranged on similar lines to those of previous years. The fee for the course is three guineas. Courses have also been arranged at the Glasgow Eye Infirmary for those interested in ophthalmology, and facilities for the study of clinical obstetrics and ante-natal work are offered by the Royal Maternity and Women's Hospital. The staff of the Ear, Nose, and Throat Hospital has arranged demonstrations on ear, nose, and throat affections, and a course in radium therapy is offered at the Radium Institute of the Glasgow Royal Cancer Hospital. A limited number of clinical assistantships are available at most of the institutions taking part in the work of the Association during the winter months as well as at other times of the year. Full particulars can be obtained from the secretary, Post-Graduate Medical Association, the University, Glasgow.

England and Wales

Maternal Mortality: A Call to Action

The Minister of Health has reviewed the action taken throughout the country in response to the memorandum on maternal mortality, issued in December, 1930, and has now sent a circular (No. 1433) to maternity and child welfare authorities commenting on the results so far observed. He finds that the number of ante-natal clinics has increased from 1,048 in 1930 to 1,340 at the end of 1933; the proportion of expectant mothers availing themselves of the services thus afforded has increased from 27.3 to 42.2 per cent., and maternity beds provided or subsidized by local authorities rose in number from 7,070 to 7,245. A satisfactory feature of this service, he adds, has been the tendency in some areas to concentrate the maternity work at the institutions transferred to county and county borough councils under the Local Government Act of 1929, by modernizing the maternity wards and their equipment, and by strengthening the medical and nursing staff employed for this work. It was originally recommended that new maternity accommodation should, where practicable, be associated with general hospitals, and recent experience has shown that it is in general undesirable to provide small maternity homes as separate units. The Minister thinks that greater use might still be made by local authorities of their power to assist expectant and nursing mothers by the supply of milk.

In spite of what has been done to improve and develop the maternity services the maternal rate has not begun to fall; it has, indeed, shown a slight tendency to rise. There are still many areas in which the maternity service is neither complete nor satisfactory, and there are few in which there is not scope for further improvement. In all areas there is probably need of more intensive efforts to educate women as to the importance of ante-natal supervision, and to make use of the facilities provided for this purpose. The Minister therefore urges local authorities to review their position in the light of the suggestions contained in the memorandum, and to take such further steps as may be necessary to complete their organization and ensure its effective working. In particular, he commends this to areas in which the maternal mortality rate is persistently high, and in which further efforts should be made to reduce the avoidable risks of child-bearing. He suggests that it would be desirable in all such areas for the local authority to call for a special report on this subject from its medical officer of health, showing what has been done as regards: (1) improving the ante-natal service; (2) ensuring that the services of a trained midwife are available for all confinements; (3) securing the provision of maternity beds for complicated cases and for patients with unsuitable home conditions, such beds to be associated where practicable with general hospitals, preferably in small units readily supervised, and for which prompt specialist services for serious cases may be made available; (4) providing facilities for the adequate isolation and separate nursing of cases of puerperal sepsis; and (5) obtaining the services of a consultant for doctors needing assistance in difficult or complicated cases. In order to encourage a more intensive study of the problem in such areas the Minister proposes to instruct suitable medical officers to make special visits to them in the near future. He hopes, therefore, that the authorities concerned will call for the preparation of special local reports at once and inform him when they are available. Arrangements will then be made for the official visits, and it is hoped that therefrom may spring a plan of action which will assist the local authority in performing its duty effectively. The Minister concludes by reiterating the view that there is a clear case for development of the maternity

services on urgent grounds of health, and offering to place the services of his Department at the disposal of those authorities which could thereby be enabled to improve conditions in their own areas.

A Nutritional Investigation of School Children

In view of a statement by the head teacher of one of the schools in Middleton, that "lack of nourishing food" was the cause in the children of an inability to concentrate, a deterioration in physique, a lowered standard of work, and an absence of vitality and pluck, an investigation of 217 unselected children in various departments of that school was arranged by Dr. S. T. Beggs, medical officer of health. Weights and heights were correlated, and shown to be average on the whole, although there were several individual exceptions. Most of the children had too little sleep, however, and the foodstuffs they received were sometimes most unsuitable. The school conditions were not altogether satisfactory, there being too much noise from adjoining classes—an important factor in feebleness of concentration. This investigation led to an inquiry being made in other schools, a questionnaire being sent to head teachers. The number of children found to be under the average height and weight amounted to 34.45 per cent. The percentage of children not receiving properly prepared meals at home was 8.61, having no milk 11.26, and having an excessive amount of tea 12.58. In 62.26 per cent. there was insufficient sleep. Overcrowding was found in 31.79 per cent., unemployment was possibly concerned in 49.67 per cent., and various physical defects were present above the average. Suitable instructions were accordingly issued to parents. The average of thirty-two estimates by clinic mothers of the cost of an economy diet weekly for a family of mother, father, and one child aged 5 was 16s. 8d., as against the British Medical Association's figure of 13s. 8d. Current food prices were shown to be higher than those noted by the B.M.A. It is concluded that the causation of ill nutrition in growing children is complex in nature, but that sufficiency of sleep is a major factor in determining the growth and development of the school child. The excessive physical defects are to be related to the nutritional state. Home management in a number of cases requires drastic correction, but the school environment also needs improving sometimes. The amount of money expended on food in the homes of necessitous cases is below the minimum for the satisfactory growth and health of the children. The mothers' estimates as regards the food requirements of a family closely approximate the B.M.A. figure, but the local prices of foodstuffs are higher than those estimated by the B.M.A. in the proportion of 24s. to 20s.

Central Midwives Board

At the October meeting of the Central Midwives Board for England and Wales the business dealt with included a letter from the Ministry of Health, enclosing correspondence relating to the action of an approved teacher who had signed wrong dates on the certificate of a candidate for examination. It appeared that the teacher admitted the error, but stated that when she signed the schedule she was seriously ill and did not confirm the dates. The Board decided to instruct the appropriate subcommittee to consider the question of removal of the name of the teacher in question from the list, and that she be invited to attend to show cause why her name should not be so removed; and that pending the hearing of the case by the subcommittee the teacher be instructed not to engage any further pupils. A letter was read from Dr. Chisholm of the Jessop Hospital, Sheffield, asking that, owing to the

difficulty of obtaining a sufficient number of district cases for training the pupils of the hospital in accordance with the Board's rules, those pupils who were general trained nurses might be permitted to take less than the prescribed number of district cases and make up the required number of twenty by taking additional intern cases. The Board replied that it could not modify the rule in the way suggested, because the grant of its certificate to a woman entitles her to practise as a midwife, and before such a certificate is granted the Board must be satisfied, as far as it can be, that the recipient is fitted to practise as a midwife. The resolution added that a possible way of remedying the shortage of district cases at present available for the pupils in training at Sheffield would be to submit to the Board for approval as teachers the names of competent midwives in the Sheffield area who could, if approved, undertake district training. The Board recorded its deep sympathy with the relatives of the late Dr. W. W. King and the late Dr. Tenison Collins, and its appreciation of the valuable services rendered by them as examiners.

Treloar Hospital, Alton

A new policy has come into being at the Lord Mayor Treloar Cripples' Hospital and College at Alton. It was decided some time back to enlarge the scope of the work, and to consider any crippled child, using the word in its widest sense, eligible for admission. In his report for the twelve months ended March 31st, 1934, Sir Henry Gauvain remarks that this policy has now fully justified itself, and has given children who would not ordinarily be admitted for a long enough period into a specialized hospital a chance of receiving efficient and sufficient treatment. Among the 162 non-tuberculous cases dealt with during the year were two cases of arachnodactyly, a congenital condition in which the long, thin hands and feet are like those of the spider monkey in appearance, and there is imperfect muscular development, with abnormal movements at many joints. Owing to the weakness of the muscles the spine cannot be held erect, and becomes markedly curved, while the sternum is carinate, and the thorax narrow laterally. When the head is lifted the back straightens out, and therefore, if efficient treatment is given, the deformity is corrigible. One child who was unable to lift herself from the recumbent position when admitted can now stand erect, and with the aid of suitable appliances made in the hospital splint shop can walk a little. Another patient had hypertelorism characterized by curious facial abnormalities, and was unable to walk; when discharged there was complete unassisted walking power. Various rare myopathies were also admitted, including five cases of progressive muscular dystrophy, three being of the pseudo-hypertrophic type. Two unusual complications after scarlet fever were observed, one being a rheumatoid arthritis and spondylitis, the other a case of hemiplegia, which occurred four weeks after the rash. Treatment has consisted of the usual orthopaedic operations and appliances, massage, and remedial exercises. Four patients with rheumatoid arthritis received injections of gold salts, and glycerin treatment was given in some cases of muscular dystrophy. A new type of splinting has been evolved in the late treatment of tuberculous disease of one or both hips where there is a tendency to adduction of the leg. This adduction deformity, which so often arises when hip disease has healed but fibrous ankylosis remains, has been hitherto one of the most trying, disappointing, and unsightly sequels. It frequently leads to severe disability, and sometimes to secondary spinal deformity. The splint comprises a padded band of sheet iron encircling the pelvis; on the sound side three duralum

struts attached to this and supporting a concave chest-piece, fitted to the thoracic convexity when the patient is in the erect attitude; and on the affected side a similar chest-piece attached to a duralumin bar, which is pivoted to the pelvic band behind the hip-joint, and twisting round the buttock proceeds down the inner side of the thigh, being attached to a metal plaque on the inner condyle of the femur, and strapped round the limb above the knee-joint. When the chest-piece on the affected side is drawn towards the chest-piece on the sound side, the leg on the affected side is abducted, and must remain abducted. In tuberculous disease of both hips the splint made on the scissors principle is equally effective; adduction of the legs is impossible, and the so-called scissor-leg deformity cannot develop. The new wards of the hospital were finished and opened for use during the year; there is now also a winter playground for ambulant children, providing complete shelter, flooded with radiant heat and ultra-violet light, and open to the air along the whole front. In the branch at Hayling Island a bathing pool has been constructed, 53 ft. long and 20 ft. wide, with a gently sloping floor, and ranging in depth from 6 in. to 4 ft. Filled with fresh sea-water each day, it has the advantage over the open sea of safety, ready accessibility, independence of tidal and weather conditions, and permitting the patients to have balneotherapy at the time of day most suitable for them.

London Medical Exhibition

The large hall of the Royal Horticultural Society at Westminster was occupied during the first five days of this week by the London Medical Exhibition, which brought together about 160 stands, representing the products of almost as many firms. The great bulk of the exhibits fell into the categories of pharmacy and foods, but surgical instrument makers were represented, as were the manufacturers of x-ray and artificial sunlight apparatus, optical and aural appliances, and orthopaedic constructions. Amid the crowd of more commercialized products the eye turned gratefully towards a few choice book-stalls, on which were displayed the wares of medical publishers; and, after all, books are as necessary to the doctor's efficient practice of his profession as any of the other commodities. Three British spas—Bath, Buxton, and Harrogate—set forth their advantages. While it cannot be said that anything revolutionary made its appearance, there was at every turn material to appeal to the intelligence, and, incidentally, to charm the eye, for the manufacturers who serve the medical profession understand as well as any the psychology of the outside of the cup and platter. It would be invidious to mention the names of any exhibitors, but out of a hundred substances, preparations, or instruments, which, it was stated, had all been produced during the past year, a note may be made of a few. They included a chocolate-flavoured preparation of ferrous phosphate in granular form; a vitamin A concentrate in moulded chocolate tablets; other tablets each containing 5 mg. of pure crystalline vitamin C; a sterile, stable solution of the acetyl ester of choline; a bee venom for rheumatism, combined in a fatty base and employed as a salve; sugar-coated granules of the active principles of calf's liver; an adhesive plaster, spread on a suntan-coloured cloth, impervious to water or acids; a portable electrocardiograph, incorporating a cathode-ray oscillograph; a metal folding shield for placing over the patient's face in mastoid operations; a stethoscope chest-end with flexible rubber resonator to which a detachable metal diaphragm is fitted; an electric bone conduction aid for the deaf; a spirit-proof thermometer case, with spring shock absorber, toughened glass lining, and pocket clip; and finally, an enamelled case containing 117 dressings of different types for the surgery.

Ireland

Milk Regulations in Northern Ireland

Creameries will be required to furnish monthly returns to the Minister of Agriculture, setting out the quantities of milk received and from whom. Strict rules are laid down as to the surveillance of herds by producers, and officials will be empowered to inspect premises, equipment, and herds, and even to have milking tests carried out in their presence. The regulations dealing with the equalization payments from the Milk Fund in respect of all milk produced in Northern Ireland, delivered to a creamery, and used for the purpose of the extraction of cream or for manufacture into butter, provide that such payment in any month shall be made by the Ministry of Agriculture as soon as possible after the average price paid by all creameries for milk so used during the month has been ascertained. The Act provides that the equalization payment shall be a sum which will raise the average price of creamery milk to 5d. per gallon in the summer and 6d. per gallon in the winter. Concerning Grade A, Grade B, and Grade C milk—that is, milk to be sold for human consumption—the regulations provide that holders of producers' licences may not produce Grade D milk upon the premises in respect of which a producer's licence for Grade A, B, or C milk has been granted. The Ministry will not, save in exceptional circumstances and subject to such special conditions as it may impose, grant a Grade A producer's licence to any person in respect of any premises if that person holds a licence for the production and sale of Grade B and C milk on those premises. There is a similar proviso against granting a Grade B licence for premises in respect of which a Grade A or C licence is held, and against granting a Grade C licence for premises for which a Grade A or B licence is held.

National Maternity Hospital, Dublin

At the recent annual meeting of the governors of the National Maternity Hospital, Dublin, Dr. Myles Keogh, acting as chairman for the Lord Mayor of the city, stated that four years ago the governors were warned that the old hospital buildings were rapidly deteriorating, and they were advised to look for a site for a new building. As a result of the efforts of some of the governors about £6,000 was raised, and the adjoining houses between the present hospital and Merrion Square were bought up. With the money received from the first sweepstakes, work on a new wing on the site of the Merrion Square houses was begun, and this was now approaching completion. For the past three months there had not been an unoccupied bed in the existing hospital. In 1930 the total number of patients treated was 9,560; so far this year the total had been 10,076. In the medical report, which was read by Dr. Coffey, assistant master, it was stated that during the past year 1,745 patients were admitted, including 368 to the gynaecological department. In the out-patient department 7,503 women and infants attended and received treatment.

Medical Inspection of School Children

Dr. R. I. G. Reid, medical inspector of schools in the County Armagh, in his report for 1933, states that while the treatment of enlarged and diseased tonsils and adenoids is carried out by the Armagh, Lurgan, and Newry hospitals a considerable portion of these cases continue to be neglected. No provision has been made for the treatment of the other defects found during the course of medical inspection, apart from the assistance given to indigent parents towards the purchase of spectacles and the dressing by the school nurse of any sores or wounds met with actually in the course of a visit. The school medical officer, with the co-operation

of the county infirmary authorities, has, however, started a small dispensary on Saturday mornings at the Infirmary. During the year fifty-five cases of chronic ear discharge were seen—a higher number than in the previous year, due probably to a larger incidence of respiratory affections during the winter and spring. Among skin diseases scabies has decreased, while ringworm, of which there were previously so few cases that the condition was not separately classified, has increased. Impetigo contagiosa has also increased, and has been particularly prevalent in the Armagh City schools. The number of eye affections remains much the same as last year, with, however, a curious increase, for which there is no obvious explanation, in the number of cases of squint and a marked increase in those of corneal opacity. The increase in goitre, in which category are included all classes of thyroid enlargement, may be largely attributed to the dry weather of last summer, which had an adverse effect on the water supplies of most rural areas; the condition has been found most prevalent in the country districts. The number of cases of speech defects is about the same as before. The total number of children on the roll was 13,928; number examined, 11,881; scabies, four; ringworm, twenty; impetigo, sixty; other skin diseases, thirty; blepharitis, eighteen; conjunctivitis, twenty-two; corneal opacity, thirty; other eye conditions, fifty-five; serious defects of vision, 807; squint, 232; defective hearing, forty-six; otorrhoea, fifty-five; tonsils requiring removal, 396; adenoids requiring removal, 272; goitre, 136; defective, sixty-one; defective teeth, 8,839; heart disease, fifty-three; anaemia, 132; mental deficiency, eight.

Midwifery Nurses and General Nursing

The committee of the Irish Nurses' Union has written to the medical associations in the Free State calling their attention to, and asking assistance in, preventing, as far as possible, the growing practice of midwifery nurses undertaking general nursing without the necessary qualifications and training. The Department of Local Government and Public Health is strongly opposed to the employment of midwifery nurses for general nursing; there is too frequently the possibility that these nurses may attend patients suffering from infectious and contagious diseases, and thus expose maternity patients to considerable danger. The whole question is likely to come before the General Nursing Council and Central Midwives Board; meanwhile medical practitioners would be acting in their own interests if they refused to recognize midwifery nurses for other than maternity work.

The quarterly court of the directors of the Society for Relief of Widows and Orphans of Medical Men was held on October 10th, when the deaths of two members were reported and one new member was elected. Special grants amounting to £87 10s. were voted to orphans to enable them to continue their education; and £665 was voted as a Christmas present to the widows and orphans in receipt of grants, each widow over 75 years of age to receive £15, those under 75, £10, and each orphan £10. Two widows of members will shortly be coming on the funds and will receive a yearly grant of £60. The chairman of the Propaganda Committee reported that efforts were still being made to persuade newly qualified medical men to join the society. The great advantages of membership were illustrated by the case of the widow of a member whose death was reported. She came on the funds in 1919 and died in June last. Her late husband had paid in subscriptions £31 10s., and the widow received £1,170 in grants from the society. Relief is only given to the widows and orphans of deceased members. Membership is open to any medical man who, at the time of his election, is resident within a twenty-mile radius of Charing Cross. Full information may be obtained on application to the secretary, 11, Chandos Street, Cavendish Square, W.1.

Reports of Societies

CONTROL OF THE BLOOD PRESSURE

In the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on October 10th, the president, Professor J. H. BURN, M.D., devoted his address from the chair to the subject of "The Control of Blood Pressure."

Professor Burn said that present conceptions of the control of the general blood pressure were based on the view that the sympathetic nerves were only constrictor in action, and the circulating hormones, adrenaline and vasopressin, only pressor in effect. Surgical treatment of high blood pressure and allied conditions, which was increasing, had been directed accordingly to the removal of portions of the sympathetic system and of the suprarenal glands, or tumours connected with them. Some success had, in fact, been achieved in two directions. Jonnesco and Bruning had found that attacks of angina pectoris disappeared in patients from whom the left sympathetic chain (from below the superior cervical ganglion down to and including the inferior cervical or stellate ganglion) had been removed; and again various observers, following C. H. Mayo, had found that the crises of paroxysmal hypertension disappeared after removal of a chromaffin tumour from the neighbourhood of the suprarenal gland. It seemed quite clear that paroxysmal hypertension must be due to the sudden liberation of adrenaline in the blood. Apart from these two directions, however, surgical treatment had not been successful. Attempts had been made to treat continuous hypertension by removal of the suprarenal gland and by removal of portions of the sympathetic system, and both these methods seemed to have failed. The attempts had not stopped at removal of the second, third, and fourth lumbar sympathetic ganglia with adjacent branches on both sides, but had recently been extended by Adson and Brown to include bilateral section of the anterior roots of the spinal cord from the sixth thoracic to the second lumbar. Some lowering of the blood pressure appeared to have resulted from paralysis of the abdominal muscles.

VARIATION IN NORMAL PRESSURE

It was time, in Professor Burn's opinion, to reconsider the theoretical basis of such attempts. He showed graphs and gave a close description of the examination by Alvarez of 6,000 university students and graduates, from 16 to 40 years of age, with a view to determining the variation in normal blood pressure. The systolic blood pressure was found to range from 85 mm. to 190 mm., and if particular age groups were taken the variation was as extensive in such groups as in the men taken as a whole. Thus, among about 1,200 men of 18 years the blood pressure was found to vary from 85 mm. to 180 mm. When frequency distributions of these blood pressures were plotted it was evident that these were approximately normal, and that blood pressure showed continuous variation, just like body height. The average height of men was about 5 ft. 6 in., but heights of 5 ft. on the one hand and of 6 ft. on the other were not considered pathological. On the other hand, there was a disposition to expect that the pulse rate of any person should be about 72 per minute when at rest, the fact being overlooked that this was only the average resting rate. Similarly, it was expected that the normal blood pressure should be about 125 mm., but actually pressures of 85 mm. or of 180 mm. might be quite normal. The standard deviation calculated from Alvarez's figures showed that 20 per cent. of men had a blood pressure greater than 140 mm., and from 2 to 3 per cent. a pressure greater than 160 mm. The observation of a high figure on one occasion was not sufficient to justify a diagnosis of hypertension unless it was known that at an earlier examination the blood pressure was much lower. If twenty-two healthy people were examined,

one of them, on the average, would have a pressure of either less than 103 or greater than 157 mm., and by the law of averages, again, one man in about every forty-four must have a pressure greater than 157 mm., but a pressure which for him was just as normal as the colour of his eyes. How many unfortunate people were going about under the impression that they were suffering from high blood pressure when in fact their pressure merely showed an unusual deviation from the mean! Did the disease of hypertension really exist, or was it a figment of the imagination? One might doubt whether a high blood pressure should be classified as a disease unless there was evidence that the pressure was continuing to rise.

PRESSORS AND DEPRESSORS

Turning to the hormones and the nerves which were commonly regarded as vaso-constrictor in action—namely, the hormones adrenaline and vasopressin and the sympathetic nerve supply—Professor Burn said that as far back as 1900 adrenaline was shown to have a vaso-dilator as well as a vaso-constrictor action. In many conditions when the blood pressure was high the administration of adrenaline caused a fall. Probably this vaso-dilator component was present whenever adrenaline acted, and it should therefore be remembered that removal of the suprarenal glands, while taking away a pressor agent, was also taking away a depressor agent. Thus it was possible that the removal of the glands might be the worst treatment for patients with continuous hypertension. In the same way it had lately been shown that vasopressin exerted a depressor effect when injected into the ventricle of the brain. Harvey Cushing demonstrated that when vasopressin was so injected—certainly in large doses—there ensued, not the sickly pallor which followed intramuscular injection, but an intense flushing of the skin and sweating. The important fact emerged from Cushing's observations that when pituitary extract was injected in large doses—20 units—into the ventricle (which might be the normal means of entry) it caused vaso-dilatation and not vaso-constriction; from which it followed that pituitary extract, like adrenaline, might play a part normally in keeping the blood pressure low. Finally, it had been shown recently in the dog that the sympathetic supply to the muscles of the hind limbs contained a large vaso-dilator component. In the laboratory, indeed, it was much easier to observe the dilator than the constrictor effect. In this connexion he recalled Michell's observations at Cambridge that the blood pressure of rowing men was usually much less than the average. Hence all three mechanisms, hormonal and nervous, commonly thought of as pressor, might also be depressor, and it seemed more accurate to think of them as controlling the blood pressure by raising or lowering it than simply as factors which raised it. To remove suprarenal glands or portions of the sympathetic system might be a treatment calculated to worsen rather than to improve a patient's condition.

VASCULAR ACTION OF ETHER

As a kind of postscript to his address Professor Burn discussed some evidence concerning the vascular action of ether when used as an anaesthetic. Although ether was much weaker in this respect than chloroform, nevertheless it weakened the heart and lessened its output. Ether also caused vaso-constriction, and because of this the coronary flow was maintained. The vaso-constriction was caused by impulses passing down sympathetic nerves, for if the ganglia were first paralysed by nicotine to prevent the passage of such impulses, ether then caused a very large fall of blood pressure. Under ether anaesthesia the periphery must have a deficient blood supply, for a weakened heart pumping blood through constricted arteries could not maintain a normal circulation. If the peripheral circulation remained poor for very long it was clear that the patient must suffer. A recognition of the serious circulatory disturbances which ether might produce should encourage the use of some of the newer anaesthetics.

ADVANCES IN CARDIOLOGY

The opening meeting of the third session of the Mid-Staffordshire Medical Society was held at Stafford on October 2nd with Mr. F. M. BLUMER in the chair.

Dr. CRIGHTON BRAMWELL of Manchester, in an address on "Some Recent Advances in Cardiology," compared the teaching of cardiology to-day with that of twenty years ago. In the province of pathology important advances had been made in our knowledge of angina pectoris. It was now generally agreed that an insufficient supply of oxygen to the heart muscle was the causal factor in this condition. The pain of myocardial infarction was so similar to that of angina of effort that there could be no doubt that both were due to the same cause. Coronary occlusion was no longer regarded as a necessarily fatal lesion, and could often be diagnosed during life. It differed from angina of effort in many respects, but the most important diagnostic features were the persistence of the pain, the signs of shock, and the electrocardiographic findings. Neuro-circulatory asthenia had attracted much attention during the war, but also occurred in civil life as the result of acute infections and focal sepsis. It should be treated by graduated exercise and not by rest. Thyrotoxicosis was a common cause of auricular fibrillation, and in some cases this type of arrhythmia was the sole manifestation of the condition. Electrocardiography had come to stay. It often afforded objective evidence of degenerative or inflammatory lesions of the myocardium in cases where the ordinary methods of physical examination proved negative. It was especially helpful in patients with coronary arterial disease. A normal electrocardiogram did not signify a normal heart, and the electrocardiographic findings must always be considered in conjunction with the clinical evidence. Radiography was now being extensively employed in the diagnosis of cardiac lesions. A radiogram could provide all the information obtained from percussion, and could do so with a much greater degree of accuracy. It provided information as to which chambers of the heart were enlarged, and thereby provided a clue to the cause of the enlargement. It made possible an inspection of the thoracic aorta throughout its whole course, and the recognition not only of dilatation but also of calcification and atheromatous changes. It revealed dilatation of the pulmonary artery and its branches which could not be detected in any other way.

In the province of therapeutics the standardization of digitalis by biological assay had paved the way to the massive dose method of oral administration. Digitalis had almost entirely replaced strophanthus, and was more useful than quinidine in most cases of auricular fibrillation. Iodine therapy in Graves's disease had greatly reduced the operative mortality, and as a life-saving measure in acute cases was comparable to insulin in diabetic coma. Salyrgan given intravenously had established a well-merited reputation in the treatment of heart failure, and would generally produce a copious diuresis in patients with oedema. The continuous treatment of angina pectoris by nitrites had been discredited, though the drugs were useful when given at such times as an attack was likely to occur. The closed mask and nasal catheter methods for the administration of oxygen marked a striking advance over the old open method, but could only be expected to relieve dyspnoea, which depended on deficient oxygenation of the blood in the lungs. Complete thyroidectomy was now being practised with a view to reducing the metabolic rate, in patients with advanced heart failure, but the value of sympathectomy and other surgical procedures for the treatment of angina pectoris was still *sub judice*.

In conclusion, Dr. Crighton Bramwell reviewed the general outlook on cardiology at the present time. Aetiology was now regarded as the most important consideration in the diagnosis of a cardiac case. Most patients with symptoms suggestive of heart disease could be classified in three groups: those with structural lesions, those with some toxic affection of the myocardium, and those who were suffering from an anxiety neurosis. All three factors might, however, be present in some cases.

CORRESPONDENCE

L'Union Internationale Contre le Cancer

SIR,—Many of your readers will be aware that a preparatory conference took place in Paris last March which had for its purpose the formation of an international union, whose main objects will be to establish close liaison between organizations concerned in the study of cancer; to combat charlatanism; to propose criteria for a uniform international system of international records; to publish occasional bulletins on matters of international importance; and to organize future international congresses.

The preparatory conference, which was convened by Monsieur Justin Godart, former Minister of Health, and President d'Honneur of the last International Cancer Congress in Madrid in 1933, was extremely well attended. No fewer than thirty-two countries (twenty European and twelve extra-European) were represented by one or more delegates. The British delegation consisted of Colonel Smallman from the Ministry of Health; Mr. Richard Davis from the British Empire Cancer Campaign; Dr. Cramer from the Imperial Cancer Research Fund; Mr. Sampson Handley from the Middlesex Hospital; and Mr. Cecil Rowntree from the Cancer Hospital.

Agreement was reached upon certain general questions of principle, and statutes controlling the organization of the union were adopted. Of these, the ones relevant to the present purpose are:

1. That each country shall be represented by two delegates, who will collectively constitute the governing body (Le Conseil de Direction), which will meet annually, so far as possible in a different country each time.
2. That the Conseil de Direction shall have power to add to its numbers up to one-third of its total membership, by election of associate members from any country.
3. That each country shall be asked to arrange for the nomination of these national delegates.

A temporary executive committee was appointed, consisting of:

France	M. Justin Godart (President).
Germany	Professor Borst.
Belgium	Professor Maisin.
Italy	Professor Lustig.
Spain	Professor del Rio Hortega.
United States	Dr. Carter Wood.
Great Britain	Mr. Cecil Rowntree

They are to conduct any necessary business until such time as the Conseil de Direction is in being. This temporary committee met in Paris in July, and provisionally arranged that the annual subscription of Governments or cancer organizations desiring to join the Union Internationale shall be one thousand French francs.

Arrangements have been made for the preliminary work in connexion with the selection of British representatives for the Conseil de Direction to be undertaken by the British delegates to the preparatory conference held last March, and the object of this letter is to ask those organizations in Great Britain which were not represented at the preparatory conference, but which will, no doubt, desire to join the Union, to communicate with me, or with one of my fellow delegates, so that a meeting may be called for the purpose of electing the two British representatives.

I should add that the Ministry of Health and the Department of Health for Scotland are sympathetic towards the objects of the proposed Union.—I am, etc.,

CECIL ROWNTREE.

9, Upper Brook Street, W.1.
Oct. 15th.

Whither General Practice?

SIR,—Might I be granted the privilege of ventilating a grievance in your columns, in order to obtain the opinions of the large body of general practitioners whom it intimately concerns?

There is to-day an increasing tendency for ante-natal, welfare, and other auxiliary medical services to encroach on the functions of the doctor whose patients belong to the lower middle class. Two recent cases in my practice illustrate this, and are only typical, I believe, of thousands of others in all parts of the country.

Case 1.—I advised a patient, whose first confinement I attended and whose infant did not thrive on breast-feeding, to adopt "complementary feeds," and gave the necessary detailed instructions. A few days later, without my knowledge, a welfare worker called on the young mother and, in a most courteous and ingratiating manner, discussed the progress of the child, casting doubts on the accuracy of my instructions. After an interval of three days she repeated her visit, to inquire about the child, and remarked that, though she could not "interfere" while I was in attendance, she could give advice when I had "ceased to attend"! This, in effect, meant that the continuous individual supervision of the infant, which I look upon as one of the chief privileges and duties of the family doctor, was to be taken out of my hands and conducted by a welfare worker. The mother did not belong to any "clinic," nor had she expressed any wish to consult a welfare worker, being both anxious and able to pay for my services. When I complained to the medical officer of health of the district he not only justified the worker's action, but tacitly admitted that, under his instructions, members of his staff paid these uncalled-for visits to mothers when births had been notified to him.

Case 2.—A patient, whose confinement was conducted by a nurse, was strongly urged by a welfare worker to take her baby to the clinic. There the assistant medical officer of health, after examination, advised hospital, but the mother expressed the wish to consult her own doctor first. Since the patient was well able to afford a doctor the welfare worker was not, in my opinion, justified in urging a "clinic," nor the assistant medical officer of health a "hospital." For the benefit of such a patient both should have advised her to select a doctor if she had not already got one.

Having held an appointment of medical officer of health and, within the last two years, organized and directed a most successful welfare centre, I do not underrate the value of "clinics," but am convinced that an over-zealous staff is often too anxious to enrol, one might almost say "press-gang," members who are quite able to afford a private doctor. "General practice" becomes increasingly curtailed, largely because of the facilities given by hospitals and various clinics which, while complaining of "abuses," do not take the necessary steps to encourage, still less order, many of their patients to obtain the services of a family doctor. A great service would be rendered to the profession if any reader would suggest a remedy for this defective procedure, more especially where the authorities are opposed to any constructive action.—I am, etc.,

Bournemouth, Oct. 12th W. SAVILE HENDERSON, M.D.

Muco-purulent Tubo-tympanic Infections

SIR,—Mr. Holt Diggle's letter in the *Journal* of October 6th encourages me to send you some remarks which I made in closing the discussion at Bournemouth, on the subject of muco-purulent tubo-tympanic infections. I suggested this subject to Dr. Rodger because I had been remarkably unsuccessful in dealing with patients suffering from this condition.

Nasal obstruction (including removal of adenoids) and nasal accessory sinusitis, if present, should, of course, be dealt with, but even after this has been done many cases

continue to discharge. It is not uncommon to find that while a central mass of adenoids has been successfully removed there still remain adhesions in Rosenmüller's fossae—a difficult condition to cure. Some patients only suffer from muco-purulent otorrhoea for a short time whenever they have a cold in the head, and these are, of course, not difficult to deal with. In some of the clinics abroad these cases of muco-purulent otitis media are regarded as tuberculous, but I am not sure whether the discharge is considered to be due to tuberculous disease of the lining membrane of the Eustachian tube or whether the patient is thought to be a tuberculous subject, and therefore unable to recover from the muco-purulent otorrhoea.

It seems to me that the trouble probably lies in air cells in connexion with the Eustachian tube. During recent years it has been recognized that there are not infrequently cells in the apex of the petrous temporal above the cochlea. In severe cases of acute purulent otitis media infection in these cells gives rise to the condition known as "apicitis," associated with severe pain behind the eye on the corresponding side and paralysis of the homolateral sixth nerve. It seems quite probable that chronic infection of these cells may be the cause of many cases of apparently incurable muco-purulent tubo-tympanic catarrh.

I have tried many methods in attempting to cure the condition—for example, the internal administration of sodium iodide in large doses, combined with the local use of peroxide of hydrogen (Plannenstiel's method). In other cases "mucidan" in various dilutions was used in the form of ear drops, but the remedy is painful and not suitable for children. Nager of Zurich recommends intratympanic syringing, drying with cotton mops, and the insufflation of boric powder or "zeroform." The method I have most frequently employed is to syringe out the anterior part of the tympanum and the Eustachian tube from the external acoustic meatus by means of a metal syringe with a bulbous nozzle which tightly fits the external meatus. The patient sits holding a basin below his chin, and the fluid syringed into the meatus passes through the perforation, down the Eustachian tube, and drips from the corresponding side of the nose. Thereafter, the fistula bag is used, just as in cases in which one suspects erosion of the lateral semicircular canal (circumscribed labyrinthitis). After the tube has been dried out by the use of the fistula bag 10 per cent. argyrol is instilled into the meatus and forced down the Eustachian tube by further application of the fistula bag. In other words, one treats the condition somewhat like a case of gleet. Theoretically, this line of treatment would appear to be very satisfactory, but, unfortunately, although the discharge lessens or even ceases for a day or two, the trouble recurs.

May I, in conclusion, say that I regret that the discussions which followed the various papers at the Bournemouth meeting had to be reported in such an extremely abbreviated form. The discussion on July 26th, after Mr. Just's paper on "Allergic Factors in Rhinorrhoea," was one of the most interesting and informative that I have ever listened to.—I am, etc.,

Edinburgh, Oct. 10th.

J. S. FRASER.

Pre-natal Diagnosis of Congenital Heart

SIR.—In the literature available to me I can find no reference to a diagnosis of congenital heart having been made before birth. My search has not been exhaustive by any means, but that there is such a possibility the following case will illustrate.

The mother, a primipara aged 27, presented herself for the first time at the ante-natal clinic on September 12th, 1934. The presentation was a vertex, and normal foetal heart sounds were heard in the usual right occipito-anterior position.

The mother had a systolic murmur in the mitral area, which had been discovered previously—during a temporary illness some time before. She gave no history of rheumatism or any allied condition, and had never suffered any symptoms of heart disease. The murmur was regarded as a functional one.

From September 12th the patient was seen every month until the thirty-sixth week, and from that time weekly until labour. During this period the foetal heart was heard in the right occipito-anterior position at each visit, and no souffles or other deviation from the normal foetal heart sounds was heard at any time. On October 2nd, at what corresponded, according to the date of her expected confinement, to the thirty-ninth week, a murmur was heard in what is regarded as the right occipito-anterior position. This murmur was asynchronous with the mother's pulse, and presented a peculiar rough and somewhat prolonged crescendo sound. As I knew no way of timing a murmur in the foetal heart, and as its other characteristics were very similar, I recorded it as a presystolic murmur.

Labour commenced on October 4th, and was normal in every respect and unassisted, the second stage occupying only fifty minutes, and she was delivered of a live male child weighing 6 lb. 4 oz. The infant was cyanosed at birth, but showed no clubbing of the fingers or toes. A systolic murmur could be heard at the base, loudest in the pulmonary area. Considering that it had been heard through the mother's abdominal wall, it seemed that it had decreased in intensity. As the infant was cyanosed, in accordance with the usual practice at the Council's maternity home, where this child was born, Dr. D. M. Cunningham, the mother's private doctor, was called in to attend the child. He confirmed the diagnosis of congenital heart. The infant died on October 6th at 10.30 a.m.; unfortunately a post-mortem was not practicable. I am indebted to Dr. Cunningham for the privilege of examining the infant at the time it was under his care.

Although the case appears at first to be merely of clinical interest, I had hoped, if the infant had survived, to endeavour to watch the changes, if any, in the character of this murmur, with a view to learning, if possible, something of its relation to prognosis.—I am, etc.,

A. W. JOHNS,

Erith, Oct. 10th.

Medical Officer of Health.

Ether Convulsions

SIR.—Having had a case of ether convulsions a few days after the publication of Dr. Sykes's letter (September 29th, p. 610), I reread it with great interest, and think that perhaps a few details about my patient may be useful to those investigating this dangerous condition. In many respects it resembled Dr. Sykes's case.

The patient was a well-grown boy aged 14, sent in as an acute appendix. He was given morphine 1/12 grain on admission, and a further 1/12 grain with atropine 1/200 grain before operation. Induction, by a few drops of ethyl chloride with eau-de-Cologne, followed by ether and oxygen, was rather delayed, owing to the boy's intolerance of ether at first. I had to go slower than usual, as he tended to cough. The surgeon commented on his rapid respiration, and the boy phoned until he had definitely had more anaesthetic than the average for such a patient. Masses of tuberculous glands were found, and there was a strong suspicion of tuberculous enteritis also, but the operation, appendicectomy, was uneventful.

Just as the last sutures were being tied, the mask raised, and the ether turned off, twitching of the face began, exactly like a bad chorea. The colour throughout was bright pink.

As the condition did not spread to the limbs no further treatment was given, other than a supply of oxygen and attention to the airway. The head had been slightly raised the whole time to help relaxation. Twitching ceased after five or six minutes.

(1) In this case, and also in another which I had in May, 1933, the same oxygen cylinder was used for several other appendix cases without any convulsion. This seems to acquit the oxygen. (2) Both these cases were not

smooth from the start. Their respiration was uneven, they did not settle well, and caused me anxiety all the time, before anything happened. (3) Both had more ether than normal, and developed symptoms at the end of the operation—that is, just after absorbing "the little more," given for closure of the peritoneum. The amount of ether given was, to the boy of 14, four and a half ounces, and to the other case, a man of 31, nine ounces, both more than my average.

I would suggest that ether convulsions are due to the presence of more than one factor at the same time. I suggest that the unsatisfactory respiration is the danger signal that indicates the presence of one of the factors, and that when this occurs special care should be taken not to give any more anaesthetic than is absolutely required by the surgeon, as the excess of ether is also, I believe, often connected with the condition.—I am, etc.,

Doncaster, Oct. 12th.

B. E. COOK.

Control of Haemorrhage in Prostatectomy

SIR,—I am much interested in Mr. F. McG. Loughnane's letter in your issue of October 13th. His findings bear out my theory as propounded in the description of my two-way catheter and vacuum-flask retainer (irrigator), published in your issue of July 15th, 1933. My article "Complete Closure of the Urinary Bladder in Cystotomy Cases," published in the *Lancet* of January 13th, 1934, describes the method fully. For the past year I have used my apparatus for continuous irrigation in acute and chronic cystitis, pre-operative treatment of bladder operations, and in selected cases for complete closure of the bladder in cystotomy cases. In all cases that have been treated in this way haemorrhage, when occurring, has been completely controlled in twenty-four to forty-eight hours.—I am, etc.,

London, W.1, Oct. 15th.

MORTON WHITBY.

Female "Bleeders"

SIR,—I was interested in the cases reported by Drs. Foulis and Crawford in the *Journal* of September 29th (p. 594), and by Dr. Leak in the correspondence columns of October 13th. The authors of the first article do not seem to have been previously aware of the possibility of haemophilia occurring in the female. Dr. Leak mentions the possibility of haemophilia being a Mendelian characteristic, but is wrong in arguing that it is probably a dominant one because it happens to have occurred in consecutive generations.

The known recessive sex-limited factors in the human race, such as haemophilia and colour-blindness, are ordinarily confined to the male sex, but are transmitted through certain female members of the family. This is one of the reasons for believing that sex itself is a Mendelian characteristic, and that in the human species the male is the mixed dominant (DR) and the female the pure recessive (RR). Thus, if the normal constitution of male and female be DrRd and RdRd respectively (where r and d are factors concerned with haemophilia), the female carrying the factor for haemophilia, though not herself a bleeder, will be represented by RrRd. Mated with a normal male, the offspring might be DrRr, DrRd, RdRr, RdRd—in other words, one male bleeder, one normal male, one female carrier, and one normal female. The female carrier will produce male bleeders as before, but the male bleeder mated with a normal female (DrRr × RdRd) will produce normal males (DrRd), or female carriers (RrRd) only.

The rare cases in which female bleeders occur are accounted for only by the union of an affected male (DrRr) with a female carrier (RrRd), in which case the children will consist of one affected male (DrRr), one

normal male (DrRd), one affected female (RrRr), and one female carrier (RrRd). In haemophilia this is particularly uncommon because of the rarity of a male living long enough to marry and have children. It will be noticed that both the family trees referred to can be explained by this simple application of Mendelism.—I am, etc.,

Sheffield, October 15th. ROBERT PLATT, M.D., M.R.C.P.

SIR,—There have been two examples of familial bleeding recorded recently in the *Journal*, each of which shows several points of interest. The first, that of Dr. Foulis and Dr. Crawford (p. 594), claims the existence of two females suffering from haemophilia. The pedigree is characteristic of a Mendelian sex-linked defect, and may well be that of haemophilia, but it is interesting that two affected brothers should reach adult life and produce families. The authors state that "a haemophilic man rarely transmits the disease to his sons or the tendency to his daughters," but the reason for this is that the haemophilic man rarely reaches adult life. The existence of a haemophilic female can be satisfactorily explained if the father is haemophilic and at the same time the mother is a haemophilia carrier, and I suggest that the mother of the two affected females should be investigated from this point of view. The chance of this occurring must, of course, be extremely small. At the same time there have been many examples of female members of haemophilia families who, though not truly haemophilic, show an abnormal tendency to bleed.

The family recorded by Dr. Leak (p. 700) probably showed an entirely different defect. If all the affected members of this family are suffering from the same abnormality then the condition is certainly inherited as a Mendelian dominant. Dr. Leak states that all the affected members suffer from fairly frequent and prolonged epistaxis, and this feature alone makes it highly probable that the abnormality is hereditary telangiectasia. It sometimes happens in this disease that the lesions are scanty and not very obvious on the skin, but I suggest to Dr. Leak that he should examine the lips, tongue, buccal mucosa, nasal mucous membrane, and the conjunctivae for the presence of the characteristic small, bright red telangiectases.—I am, etc.,

Leeds, Oct. 15th.

HUGH G. GARLAND.

SIR,—I was greatly interested in the cases quoted by Drs. M. A. Foulis and J. W. Crawford, and by Dr. W. N. Leak.

The haemorrhagic diseases are as yet the most unsatisfactory section of haematology, because our knowledge of several of the factors is incomplete. We do not know, for instance, the full mechanism of the coagulation of normal blood. In diseased states there are many anomalies which cannot be explained. One of the greatest difficulties is the inconstancy of the phenomena which may be associated with thrombocytopenia. For example, blood from which the platelets have been removed will not clot unless it is taken at the height of digestion, whereas the blood from a thrombocytopenic patient will sometimes clot normally when taken fasting. Further, even if the coagulation time and bleeding time are normal it cannot be stated that a patient will not bleed excessively when exposed to injury.

Cases of female "bleeders" are usually examples of haemorrhagic diathesis. The females of haemophilic families occasionally bleed somewhat readily, but never to the extent that the males do. According to Bulloch and Fildes, cases of haemophilia apparently transmitted by males are explained by the wife being of bleeder stock. I should like to suggest, therefore, that the genealogies

quoted by your contributors are examples of the rare hereditary haemorrhagic diathesis, sometimes called constitutional haemogenia or hereditary pseudo-haemophilia. The latter is a bad name, because the condition has nothing to do with haemophilia. As its name implies, it is a hereditary disease, transmitted directly from generation to generation, affecting females as well as males.

In my view there are four simple tests which should be performed in the diagnosis of these blood states: (1) a platelet count, (2) the coagulation time, (3) the bleeding time, (4) the capillary resistance test. In haemophilia the coagulation time is greatly prolonged, the other tests being normal. In haemorrhagic states the coagulation time shows no gross change, though the clot may not retract normally, while the other three tests give abnormal findings, chief of which is the low platelet count, which may be found especially at the time of the occurrence of the haemorrhage.—I am, etc.,

Brighton, Oct. 14th.

L. IVAN M. CASTLEDEN.

Residual Infection of the Jaws

SIR,—The article on "Residual Infection of the Jaws" by Mr. R. S. Taylor (*Journal*, September 22nd, p. 553) recalls the fact that this condition was one of the problems that provoked Novitzky to devise his technique for removing teeth over twenty years ago in San Francisco. He was very frequently defeated and disappointed with his attempts to relieve patients' symptoms by the removal of infected teeth. These defeats and disappointments, he concluded, were due to the fact that infections still persisted in the jaws after tooth extraction by the ordinary pulling method, because the pathologic soft and hard tissues—the result of infected teeth and pyorrhoea—were not eliminated, and could not be eliminated, by the mere removal of the infected tooth. He then devised a new method of removing teeth. Suitable incisions were made, a flap of muco-periosteum was turned back, the outer plate of bone encasing the teeth was chiselled away, and then the teeth were removed. This gave visible and instrumental access to the region about the root ends, which then could be removed immediately and thoroughly by means of curettes or other instruments. The flap was restored to its former position and sutured in place.

Having employed this technique in my own practice for about eighteen years, I find that it accomplishes a great deal more than Novitzky anticipated. It accomplished more than any other technique devised for the elimination of infected teeth and for shaping a suitable bony base for artificial tooth plates to rest upon. It changed the status of those who employed it from that of "tooth pullers" and "tooth extractors" to that of surgeons. It is the technique employed in the Mayo Clinic by Gardner, in Chicago by Molt, and by the leading oral surgeons in the United States and Canada. When this technique is employed properly, under block anaesthesia with novocain, it eliminates all of those not infrequent catastrophes that follow the ordinary method of tooth pulling with a whiff of gas and oxygen.

Molt, in a paper on the elimination of oral foci of infection in the *British Journal of Dental Science* (1921, p. 179), states:

"Far from being infinitesimal [the percentage of edentulous areas showing radiolucency—presumably pathological] it is on the contrary large enough to be a vital argument in favour of thorough curettage and to explain many of the failures in clearing up systemic lesions, by extraction, when the operator has removed the teeth and ignored the adjacent infected tissue. During the last two years I have cultured about 3,000 granulomata removed under strict surgical asepsis with the open view procedure [the Novitzky technique], and practically no negative reports are shown. The predominating organism, as would be expected, is the streptococcus, mixed in many cases with staphylococcus, diplococcus, and micrococcus

catarrhalis. This holds true of bone specimens taken from areas radiographically disclosed when remaining pathology has been suspected, and in many of which we have been able to check our diagnosis with old radiograms. The assumption is justified, therefore, that since granulomata are themselves infected tissue, and since apparently regenerated bone, displacing uncuretted masses, retains that infection, only complete extirpation will avoid the pathogenetic possibilities, and any method that will achieve this result is good practice."

Again (*Dental Cosmos*, 1921, p. 1009) he writes that:

"Cases are on record of areas of residual infection found existing twenty-five years after the removal of diseased teeth without curettage, and their elimination has greatly benefited their host."

In another paper in the *Dental Cosmos* (1923-4):

"The author, in an examination of over 1,100 radiograms of areas, many of them giving a history of past infection, previous to extraction, found 40 per cent. showing evidence of remaining pathologic condition. Inasmuch as these areas found in the site of past extraction, where no curettage or inadequate curettage has been done, practically invariably yield cultures of the pathogenic micro-organisms, and the bony structure found in these areas simulates in every way necrotic bone, we can but consider this prima facie evidence of the fact that the surgery is incomplete."

Shearer (*Journ. Amer. Dent. Assoc.*, 1924, p. 272), in an examination of 1,800 patients during twelve years, found 527 cases in which knife-edges of bone persisted along the alveolar ridge.

The medical practitioner who appreciates the influence of dead teeth and pyorrhoea teeth and their contribution to systemic and organic disturbances, and advises their elimination, may profitably bear the previous observations in mind and consider the following. After the age of 40, nine out of ten persons have infected teeth, and four out of five have pyorrhoea of some degree or other. Pyorrhoea teeth are encircled with an infected pyogenic degenerated dental ligament. The encasing bone is infected—in extreme cases to a depth of a quarter of an inch. Teeth that are removed by the ordinary pulling method in most instances only stir up the infection, leaving this just mentioned infected bone and infected pyogenic membrane behind. This is most frequently sealed in by the healed covering gum, while the infecting process continues undisturbed. The literature reciting experiences similar to those of Molt, Shearer, and Gardner, and supporting the same observations, is extensive.—I am, etc.,

London, S.W.19, Oct. 12th.

ALONZO M. NODINE.

Medical Benevolence

SIR,—At the Royal Surrey County Hospital, when a death occurs in the person or the family of a member of the staff, we have recently adopted the practice of making a collection for a medical charity instead of sending a wreath, a notice to this effect being inserted in the report of the funeral in the local paper. This idea probably is not original, but hospitals which do not already carry it out might well do so, and benefit a deserving cause rather than the florist.—I am, etc.,

Guildford, Oct. 13th.

G. H. STEELE.

SIR,—I am sorry to strike a discordant note, but I must confess that the hardy annual appeal of Sir Thomas Barlow on behalf of the Royal Medical Benevolent Fund inspires me with a feeling more of irritation than of sympathy. I am irritated, not because Sir Thomas rattles his begging bowl under my nose so regularly, but because he should have to do so. Why in the name of all that is charitable, if the cause is a good one, should it have to be laboured so? As there is not a vestige of a doubt that the cause is a good one, why cannot the unfortunate of the profession be provided for with decency and comfort

once and for all, and we ourselves be spared this continual harrowing of our feelings with tales of want and distress?

It may seem rather ungracious to carp at the British Medical Association for the part it has played, but I cannot help thinking that if the cause of the infirm and the needy had been fought with half the zeal of the fight for the odd sixpence on the capitation fee, this wretched tale of destitution would have drawn to a close long ago. If it is the desire of the profession to provide decently for its own poor—and there can hardly be any doubt of that—the problem is simply one of organization and the technique of money collecting. If results are anything to go by the present technique seems to fall lamentably short of perfection.

I have been a little surprised that in eighteen years' qualified life I have never once been personally approached and asked to subscribe to the fund. Postal appeals, circulars, and notices in the *British Medical Journal* there have been in abundance. But these are not much use. They have to compete on our breakfast tables with a heap of other more or less deserving appeals, and do nothing to secure a settled permanent income for the fund. It is the personal touch that gets the money.

I was once rash enough to think that, when some time ago panel practitioners agreed to a regular deduction from their pay, we could at last go to bed with easy minds. But no. Along come Sir Thomas Barlow and other kind-hearted people, cap in hand, disturbing our rest with the same tale of unrelieved distress as before. The technique I should suggest would be something as follows.

Subscriptions should be in the nature of a levy on the whole profession. It should be a fair levy. And to be fair it should be universal and in proportion to means, and as compulsory as public opinion can make it. The voluntary levy to which panel practitioners at present submit should be abolished. It is not quite fair, as those with small panels or no panels at all are not uncommonly better off than those with big panels. Then an undertaking, written if need be, should be obtained from every medical man in the country to contribute, say, one-fifth of 1 per cent. of his assessable income to the headquarters of the fund. In every Divisional area of the British Medical Association one representative of the fund should be appointed—a person who should combine the savvy of an archdeacon with the persistence of a commercial traveller. He would be notified when a subscription was in arrears, and it would be his particular duty to see that it was paid. The task of winning over any residuum of obdurate or recalcitrant non-subscribers might be left to the persuasive eloquence of volunteers from that distinguished section of the profession, retired or otherwise, whose good fortune it is to have plenty of leisure. And I think I should make Sir Thomas Barlow tormentor-in-chief.

I cannot believe that anyone would object to this or some similar scheme. The amount raised, if everybody contributed, could be calculated to meet all needs; the present excellent but somewhat exasperating mendicancy could be silenced for ever, and yet the individual contribution would be so modest that not one of us need smoke a cigar the less. The medical profession, in spite of our many complaints, as a whole is well-to-do. The financial crash which beggared so many of our own social rank has turned none of us on the streets. It is a shame and a reproach on us that our colleagues in misfortune, who have the justest claim on our purses, should be dependent for their barest necessities on spasmodic appeals for our bounty.

Sir Thomas wants to give thirty shillings to each for Christmas! Surely this can be bettered. For any sake let some new scheme be set going so that we, the fortunate, who have never known want, can at least sit down to our own comfortable dinners without getting the taste of the orphans' boots and the widows' coals in the soup.—I am, etc.,

A. J. HAWES.

The Swab in Diphtheria Diagnosis

SIR,—Your correspondent Dr. E. James (*Journal*, August 4th, p. 230) asks: "How much longer is the swab to be relied upon in the diagnosis of faucial diphtheria?" After twenty-five years of experience as a pathologist in private practice I maintain that the following is sound advice in regard to the above question.

To begin with, everything depends on how the swab is taken. The swab itself must be made *secundum artem*. The wool must be tightly rolled on the stick, and the distal end should be fairly pointed. To use a loosely rolled plug of wool, to merely touch the suspected spot with the broad distal end thereof, is almost useless, because when attempting to inoculate the medium in the test tube that spread-out distal end most likely will not come into contact with the medium at all. With a properly made swab it is the side, not the tip, which is laid on to the suspicious spot; then the stick is given a vigorous twist whereby the entire lateral surface is brought into contact with the infected spot. Similarly, when the swab is brought into contact with the medium, the side of the swab (not the tip) is laid on at the bottom end of the tube, when, by means of a twist, and while dragging the swab along the surface of the medium, the entire lateral surface of the swab makes an intimate contact with it. Another fallacy lies in the fact that a certain amount of pluck and skill is required to touch the spot on the fauces, say, of a spluttering and coughing child. To turn one's head away, and to shut one's eyes for fear of being bombarded with the patient's splutterings does not lead to the obtaining of a satisfactory swab.

Another essential lies in the conveniences offered by the laboratory undertaking the examinations. The laboratory of a clinical pathologist, in private practice, must be open day and night, like the surgery of the general practitioner. If a throat swabbing arrives at 11 p.m., or any other time, somebody must be on the premises who has been trained to apply the swab correctly to the medium. A prompt report is then the next essential. The general practitioner must receive his report before 9 o'clock the following morning, before he starts his rounds, and this must include Sundays and holidays. Working under this scheme I have been able to give the following very definite advice to general practitioners. Any patient clinically seriously ill with a suspicion of diphtheria must be given antitoxin at once. When not seriously ill neither patient nor a household should be alarmed before the pathologist's report has been received.

In these days of keen competition and of general depression nothing damages a general practitioner's reputation more than to become known as an alarmist, apart from putting patients to the extra expense for antitoxin injections and causing the associated mental anxiety of the household concerned—especially if the patient happens to make a complete recovery within a day or two of the first symptoms.—I am, etc.,

Sydney, N.S.W., Sept. 12th.

ALFRED E. FINCKH.

SIR,—The recent lengthy correspondence in your columns on "The Swab in Diphtheria Diagnosis" has dealt with many problems of the disease: two interesting points in particular were mentioned but not elaborated—namely, virulence and immunity. Dr. James suggests that carriers of organisms morphologically resembling the Klebs-Löffler bacillus may help to immunize the susceptible population; but what guarantee is there that such organisms, whilst being apparently harmless to their host, may not prove fatal to a person with less immunity or resistance? At the bedside of an "acute sore throat" it is important to assess three factors before prescribing any treatment:

(a) The type and virulence of the infecting organism, which only the swab can identify.

(b) The resistance and/or immunity of the patient, which may be indicated by his history. It seems scarcely necessary to emphasize the importance of the pulse rate in assessing the balance between this and the virulence of (a).

(c) The time factor, which may vary with differences of (a) and (b). We have all seen the fulminating cases, and also those which are moribund before the relatives send for a doctor. Incidentally I agree with Dr. Stollott that these two types of case form the majority of fatalities, admitted to hospital or not.

These, then, are the primary criteria for the administration of antitoxin, and not the swab. The latter will be the only guide in cases where (a) appears to be low, (b) to be high, and (c) short. No harm will be done if antitoxin is given to streptococcal or spirochaetal (Vincent's) throat; on the contrary, it has been my experience that this form of non-specific therapy is often followed by immediate and dramatic improvement in such cases.—I am, etc.,

Greenford, Oct. 14th.

ALISTAIR R. FRENCH.

*. This correspondence is now closed.—ED., B.M.J.

Publicity

SIR,—Where are we? When will any one of us, not of the shrinking dove type, find ourselves confronted with a charge of "advertising"? Dr. Abrahams has put his thumb down on a sore spot which is liable to become very sore indeed. . . .

Some of us, whether or not we are regarded as authorities, do get quoted in the lay Press. And why not? So far as I am aware, it does nobody any harm. Once upon a time I wrote you a very nice truthful letter. It was quoted in several lay newspapers, whereupon a raw carrot and onion juice practitioner made a most violent attack upon me. It was all very amusing: I got a lot of publicity; and no one was a ha'porth the worse. . . .

In my time I have been something of an authority on Regional Medical Officers, concerning whom I have written freely. My remarks have been referred to in the lay Press. And why not? The subject is a professional one; but also it is of considerable interest to that part of the public which is insured. I submit that my efforts were wholly beneficial. I am still friendly with R.M.O.'s, who, so far as I can make out, have become better, if not noticeably more humble, men.

I suggest that our Authorities should do a little fresh thinking, and consider once more the question of "advertising." We are all guilty of it. Every brass plate is an advertisement. Every hospital report contains advertisement. Most bulletins of the Great are advertisements. And they are all completely harmless. Are the matters to which Dr. Abrahams refers really harmful? I submit that they are not. Doctor affairs are "news"; and news will be printed whether we like it or whether we don't. Surely, then, it is desirable that it shall be presented truly instead of, as too often, in a garbled form. Professional methods have progressed; professional manners seem to have changed little since the days when Ambroise Paré was a young man. We still are over-much hampered by the Gentlemen of the Long Robe!—I am, etc.,

Walsall, Oct. 14th.

FRANK G. LAYTON.

SIR,—With the excellent advice given by Dr. Adolphe Abrahams in last week's *Journal* (p. 699) there will surely be general agreement. As we needs must suffer, let us suffer with dignity and in silence. Equally, Dr. Abrahams commands our sympathy in the irritating telephonic inquiries thrust upon him

by enterprising journalists. Occasionally it is possible to make an effective protest against these intrusions. Here are two personal experiences. Voice: "I am speaking on behalf of newspaper so-and-so, and in view of a recent inquest on a man who died while taking a hot bath after a full meal I want to know whether the medical profession considers such a practice dangerous to life." Reply: "I really could not pretend to say." Voice: "Would you be good enough to suggest a doctor as a specialist in such a subject?" Reply: "There is no need to ask a doctor, for the question can be settled by yourself. Thus, when you go home to-night have a really good dinner, then take a hot bath and see what happens!" Result: no more inquiries from that newspaper. Again, a sharp female voice: "I want to ask you a question about infant feeding." Reply: "I know very little about it." Voice: "But aren't you a Baby Specialist?" Reply: "No, madam, thank Heaven, I'm a full-grown man!" *Tableau*.—I am, etc.,

London, Oct. 16th.

H.

Obituary

ROBERT J. GITTINS, M.D., M.R.C.P.

Pathologist to the Children's Hospital, Birmingham

We regret to announce the death on October 7th of Dr. R. J. Gittins, pathologist to the Children's Hospital, Birmingham. While attempting to save his young son from drowning in the River Severn, near Upton-on-Severn, he was himself drowned. Dr. Eileen Gittins, his wife, made a gallant attempt to rescue them, but they were dragged under by the strong current, and she could not reach them. Robert John Gittins was 39. A native of Birmingham, he was educated at the King Edward VI School and Birmingham University. He served in France during the war and won the Military Cross. In 1919 he returned to Birmingham, and in 1922 graduated M.B., Ch.B. He later took the M.D. degree and the D.T.M. and H., and became M.R.C.P. in 1930. In 1924 he went to India to take charge of the Friends Hospital at Itarsi, C.P. His wife was there with him as medical officer, and they did valuable work, not only at the hospital, but in connexion with welfare and social hygiene schemes over a wide area. They returned to Birmingham in 1929.

A senior colleague, L. G. P., sends the following appreciation:

Robert Gittins was one of a group of brilliant young paediatricians which during recent years has been associated with the Children's Hospital at Birmingham. Both he and his wife, who showed such wonderful bravery at the time of his accident, were students at the Birmingham Medical School, and spent five years in medical missionary work in India, where he came to realize the importance of pathological research and his own inability to carry it out satisfactorily. Returning to England Gittins devoted the remainder of his life to the study of the pathological aspects of paediatrics. He was appointed pathologist to the Children's Hospital in 1930, and so excellent was his work that in January of this year his appointment was confirmed on a whole-time basis. He carried out all the pathological work in the series of studies of anaemia which recently appeared in the *Archives of Disease in Childhood*, and was solely responsible for the work on leukaemia which has everywhere been regarded as a notable contribution to the cytology of the leucocyte. This work is marked by careful and accurate observations, and an attention to detail which was typical of the man. He was devoted to research, for he had a passionate desire for truth;

indeed, the desire dominated his whole life, and he was prepared to follow wherever the search for it might lead him, however difficult the course. This wholeheartedness brought him the affection of all who knew him well. He had a lively sense of humour, revelled in manly exercises, loved nature, the sea being perhaps his chief delight; indeed, on a series of week-ends he had sailed the boat from which he dived to his death from Padstow to Worcester. He was prepared to argue on either side on many controversial subjects, although tenacious even to a degree of obstinacy where principles were concerned. Nowhere did this character show itself better than in his championship of those in less favoured circumstances than himself, and it is not to be wondered at that his laboratory assistants would do anything for him. With all these things he was somewhat of a mystic, and his personal appearance bore out his spiritual characteristics, for he had those light blue eyes which appear to look far into the future and the fair hair of his Nordic ancestors. His last public appearance was in one of the series of post-graduate demonstrations at the commencement of the new session of the Medical School, when he spoke on pulmonary tuberculosis as a foe of little children. He felt strongly, even passionately, that the medical profession as a whole did not realize the deadliness of tuberculosis in childhood, and took every opportunity of trying to enforce this view. Two days later he gave his life in an unsuccessful attempt to save his second child from drowning. We who knew him realize how gladly he did this, and that he would have done it just as gladly for any child in like need. If he had lived Gittins would have gone from strength to strength, and would have been recognized as a great man in the sphere which he had chosen. His colleagues and friends and all who listened to the tributes paid to his goodness in the Friends Meeting House, Bull Street, Birmingham, on Friday last, know that by his life and death he had already achieved greatness; indeed, the manner of his being cannot better be described than in the words of those old Puritans who were his spiritual forebears: "So he passed over, and all the trumpets sounded for him on the other side."

"Nothing is here for tears, nothing to wail
Or knock the breast; no weakness, no contempt,
Dispraise, or blame, nothing but well and fair
And what may quiet us in a death so noble."

F. V. BEVAN-BROWN, M.D., M.R.C.P.

Physician to the Christchurch Hospital, New Zealand

Dr. Frederic Vivian Bevan-Brown, who died of uraemia at his home in Christchurch, New Zealand, on October 5th, was the second son of the late Mr. C. E. Bevan-Brown, the well-loved head master of the boys' high school of that town. On leaving school Dr. Bevan-Brown began his medical studies at Canterbury College, Christchurch, after which he came to London and entered Guy's Hospital as a student. He qualified in 1913, and proceeded to hold the posts of out-patient officer and house-physician at Guy's. At the outbreak of war he joined the R.A.M.C., remaining in that corps until after the armistice, and serving both on the Western Front and in Mesopotamia. On returning to Guy's Hospital he served as a medical assistant, and took the diploma of M.R.C.P. and the degree of M.D.Lond in 1930. He then returned to Christchurch, New Zealand, in which town he worked as a consulting physician up to the time of his final illness. He was honorary physician to the Christchurch Hospital, where his teaching was greatly appreciated by a long series of house-officers, and his medical services were of constant value to those under his care. His enthusiasm as a physician was an inspiration to all around him, and he contributed many original papers to local

medical societies, the diseases of the thyroid gland and the relation between the psychic and physical sides of disease being his special study. He was closely connected with other medical institutions in his native town, such as St. George's Hospital, the Karitane Hospital, and the local branch of the St. John Ambulance Association. In addition to these activities, Dr. Bevan-Brown was a very active member of the Chapter of the Christchurch Cathedral, to which he was appointed lay canon some years ago.

His death, which occurred after a very brief illness, comes as a blow to his many friends both in New Zealand and in London; at the age of 46 he had achieved more than is permitted to many, and his enthusiastic optimism will be long remembered.

F. A. SAUNDERS, F.R.C.S.Ed.

Medical Superintendent, Prince Alfred Infirmary, Grahamstown

We regret to record the death, on August 26th, at the age of 76, of Dr. Frederick Anastasius Saunders, an outstanding personality of Grahamstown, Cape Province, and a member of the British Medical Association for nearly fifty years.

Born in London, he received his medical education in Edinburgh and at University College, Liverpool. In 1882 he obtained the diplomas L.R.C.P. and S., and in 1884 the F.R.C.S.Ed. After practising in Fifehire he went out to South Africa in 1892, and started general practice in Grahamstown, where he remained until his death. He soon became renowned as a bold and skilled surgeon, and then, as medical officer of health for many years, achieved remarkable successes, abolishing slum properties and segregating lepers. In 1912 he was appointed medical superintendent of the Prince Alfred Infirmary. This was shortly after he joined the staff of the old Albany Hospital, and in two years had raised enough money to place it on a good basis. Elected to the British Medical Association in 1885, he was president of the Cape of Good Hope Eastern Province Branch in 1926-7.

From 1886, when he joined the Fife Light Horse, Dr. Saunders took an active interest in the Volunteer and similar movements. Three years later he obtained a commission in the West Yorks Regiment. In 1893 he was adjutant of the First City Volunteers, Grahamstown, and afterwards held various military appointments. He took part in the Boer War, receiving the Queen's medal with three clasps and the King's medal with two. He was finally honorary colonel of the 1st City Regiment, Grahamstown, and honorary major of the 3rd West Yorks Regiment. In Masonry he was district grand master of the Eastern Province, Scottish Constitution, 31st Degree. Outstanding characteristics were his forcible personality and abounding generosity. Apparently indefatigable, thanks to a fine physical constitution and enthusiasm for athletics, he took but few holidays. Industrious reading of new books and periodicals, as well as close comradeships with medical workers and friends in the Medical Association of South Africa, rendered post-graduate study unnecessary for him, and kept him fully up to date in his professional work. He was for some years honorary secretary of the Royal Society of Tropical Medicine and Hygiene of South Africa. Dr. Saunders attracted a large circle of friends, and actively supported the general interests of his adopted town, in which he did good work as a magistrate.

Dr. DAVID ROBERT POWELL-EVANS, who died at his residence in Wimbledon on October 11th, had been a member of the British Medical Association for forty years, and had filled various offices. Born in 1862, he received

his medical education at Liverpool and Charing Cross Hospital, obtaining the diploma L.S.A. in 1890 and the M.R.C.S., L.R.C.P. ten years later. His early appointments included those of clinical assistant to the Samaritan Free Hospital for Women and Children, and to the London Throat Hospital. He started general practice in Wimbledon in 1891, and for some time was medical officer to Wimbledon Hospital. He was medical officer and public vaccinator to the North Wimbledon district of the Kingston Union. Dr. Powell-Evans joined the British Medical Association in 1892, and was a representative at the Annual Meeting of the Association in Birmingham in 1911. He was chairman-elect of the Wandsworth Division in 1912-13, Wimbledon appearing as the "Wimbledon Section" of the Wandsworth Division in the 1912 *List of Members*. In the following year he became chairman of the Wimbledon Division, the Division then belonging to the Metropolitan Counties Branch. He was vice-chairman of the Wimbledon Division of the new Surrey Branch in 1914-15, and chairman of the Kingston-on-Thames Division in 1925-6. A man of large sympathies and wide experience, he was popular with his colleagues and patients. A prominent hobby of his was golf, and he was one of the leading members of the Raynes Park Golf Club. He was a P.M. of the Chère Reine Lodge of Freemasons, and had been president of the Wimbledon Medical Society. Dr. Powell-Evans married twice, and leaves a widow and four sons, the eldest of whom succeeds him in his practice. He had expressed the wish that money which would have been expended on wreaths at his funeral should be sent to Epsom College, of which he was a life governor.

We regret to record the death, on October 11th in London, of Dr. JAMES CRAWFORD CRAIG, at the age of 56. Dr. Craig received the degree of M.A. at the University of Edinburgh in 1895, and, after holding the Grierson bursary in pathology in 1907, qualified M.B., Ch.B., with honours, a year later. He took the D.P.H. of the English Conjoint Board in 1910. Before settling down to general practice in London, Dr. Craig had held appointments as house-surgeon to the Royal Maternity and Simpson Memorial Hospital, Edinburgh, and surgeon to the Royal Buckinghamshire Hospital, Aylesbury. He was for some years clinical assistant at the Central London Ear, Nose, and Throat Hospital.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Ernest Basil Verney, M.B., F.R.C.P., Sheild Reader in Pharmacology and lately Professor of Pharmacology at University College, London, has been elected into a Professional Fellowship at Downing College. Frank Goldby, M.B., M.R.C.P., of Caius College, University Demonstrator in Anatomy, has been elected into a Fellowship at Queen's College.

The following candidates have been approved at the examination indicated.

Physics is Modern Radiology and Electromagnetism.—(Part II): J. D. P. B. Boyd, A. A. Dunlevy, M. Kahn, W. D. C. McCune.

UNIVERSITY OF LONDON

At its meeting on October 10th, with Lord Macmillan in the chair, the University Court was informed that the Surrey County Council, acting on the recommendation of its education committee, had decided to make a grant of £50,000, payable over ten years and subject to the approval by the County Council each year, towards the erection of the new university buildings in Bloomsbury. The Court also learnt of a grant towards the same purpose of £10,000, payable over ten years from the Hertfordshire County Council. The Court has conveyed its most cordial thanks to the councils and education committees of Surrey and Hertfordshire for these munificent gifts. It has also accepted, with gratification, a donation from the Worshipful Company of Turners towards the ceremonial hall to be built on the Bloomsbury site.

The Semon Lecture

The Semon Lecture will be delivered on Thursday, November 1st, at 5 p.m., at the Royal Society of Medicine by Mr. Herbert Tilley, consulting surgeon to the ear and throat department of University College Hospital. His subject is "Inflammation of the Maxillary Antrum and other Accessory Sinuses (Some Clinical Manifestations of its Pathology)." The chair will be taken by Mr. W. M. Mollison, president of the Laryngological Section of the Royal Society of Medicine.

UNIVERSITY OF SHEFFIELD

The Council of the University at its meeting on October 12th received the resignation of Professor Graham Simpson from the chair of surgery, and of Mr. H. B. Yates from the lectureships in surgical anatomy and surgical pathology, and the tutorship in surgery. Mr. Ernest F. Finch, M.S., F.R.C.S., was appointed to the chair of surgery.

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following candidates have been approved at the examination indicated:

FINAL MEDICAL EXAMINATION.—(Part I, *Materia Medica and Therapeutics, Pathology and Bacteriology*): M. R. W. Spacek (passed on high marks), S. E. M'Connell, R. F. Cantan, H. FitzG. Sloan, S. H. Morrison, D. P. Beckett, Margaret Perry, H. Elliman, P. L. van Aardt, D. H. A. Irwin, J. M'Quillan, J. R. Shapiro, R. S. MacL. Cooke, H. W. W. Good, N. J. Smith, C. Eppel, A. E. B. de Courcy Wheeler, N. Jackson, Eithne M. O'Connell.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Bradshaw Lecture

The Bradshaw Lecture on "Haemochromatosis" will be delivered by Dr. J. H. Sheldon at the College, Pall Mall East, S.W., on Thursday, November 1st, at 5 p.m.

FitzPatrick Lectures

Sir Humphry Rolleston will deliver the FitzPatrick Lectures on the "History of the Endocrine Organs" at the College on Tuesday and Thursday, November 6th and 8th, at 5 p.m.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly council meeting was held on October 11th, with the President, Sir Holburt Waring, in the chair.

Mr. L. R. Broster was admitted a member of the Court of Examiners.

Mr. F. J. Smith, late of Bristol Grammar School, was admitted the fifth Macloghlin Scholar.

Mr. W. R. L. Harrison of Epsom College was nominated as the forty-second Jenks Scholar.

It was reported that the Sir Gilbert Blane Gold Medal for 1934 had been awarded to Surgeon Lieut.-Commander T. C. H. Neil, R.N.

Mr. F. W. Bentley was reappointed Bernhard Baron Scholar for a further period of six months.

A diploma of Fellowship was granted to Mr. J. B. Pennybacker (Edinburgh).

Diplomas of Membership were granted to Norman Angel (Birmingham), R. C. F. Catterall (Cambridge, and University College), G. B. Davis (King's College), and C. Ratnayaka (King's College).

The following appointments were made for the Primary Fellowship Examination to be held at Madras, beginning on December 27th: Lieut.-Colonel K. G. Pandalai (Assessor in Anatomy), Major S. L. Bhatia (Assessor in Physiology), and Professor P. K. Koshy Avargal (Superintendent of Dissections).

The Council adopted the annual report to Fellows and Members, which will shortly be circulated to those who have expressed a wish to receive it.

WELSH NATIONAL SCHOOL OF MEDICINE

The new laboratories of *materia medica* and *pharmacology* in the department of preventive medicine at the Welsh National School of Medicine were opened on October 12th by Sir William James Thomas, donor of the building. On the evening of the same day Professor G. Grey Turner, M.S., F.R.C.S., delivered the opening address for the new session.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

GOODWILL. AGREEMENTS TO REFRAIN FROM PRACTISING

The subject of goodwill and restrictive agreements is important not only to partners but also in every other working relationship between doctors. It is discussed here because it follows logically on a discussion of the relation of partnership, but it belongs equally to every other section of this article.

In a commercial business, carried on with the object of manufacturing or selling goods, the goodwill may be as tangible an asset as the firm's capital. Long ago, in *Crutwell v. Lye* (1810), Lord Eldon said that the goodwill which had been sold by a certain firm was nothing more than the probability that the old customers would resort to the old place. Later decisions have given the word a much wider meaning, and in *Trego v. Hunt* (1896) Lord Macnaghten said that the goodwill was often the very sap and life of the business, without which it would yield little or no fruit; it was the whole advantage of the reputation and connexion of the firm, which might have been built up by years of honest work or gained by a lavish expenditure of money. In *Hill v. Fearis* (1905) Mr. Justice Warrington said that goodwill was the advantage of being entitled to represent oneself as carrying on a business which had been carried on for some time previously. The name of the firm in a commercial business usually has a definite money value. For instance, it is obvious that for a company manufacturing biscuits the right to call itself Messrs. Huntley and Palmer would be worth many thousands of pounds. For this reason, in the very improbable event of Mr. Huntley and Mr. Palmer dissolving their partnership, neither would be entitled to continue selling biscuits as Messrs. Huntley and Palmer without paying the other his share of the value of this privilege. Moreover, if Mr. Palmer decided to start in business by himself, and sold his share of the goodwill to Mr. Huntley, he would not be entitled by law directly to solicit customers of the old firm to deal with him, and so take advantage of the connexion and his knowledge of it, but must behave as a complete newcomer into the market.

The goodwill of a medical practice is, on the contrary, a purely personal one, depending almost entirely on the confidence which the patients repose in the partner himself. A medical firm does not advertise; it is not known by a trade name; and it cannot, ethically at any rate, solicit custom. The goodwill consists in the partners' individual connexion, and when a doctor buys a practice or a partnership he merely buys an introduction, an exclusive recommendation and the exclusion of the seller. The goodwill, in the legal view, has no realizable value. If one partner, who has paid a premium, withdraws before the date fixed for the expiration of the partnership he may possibly be able to claim back a part of the premium corresponding to the unexpired term, but this is only what he has paid in order that he may share in the profits. True, the profits could not be earned without the goodwill, but he is not considered to buy with his premium goodwill, but only the opportunity of earning and sharing profits.

When the partnership expires the goodwill is not an asset which can be sold and divided among the partners. If a partner dies his representatives cannot claim anything as his share of the goodwill; the survivors need not retire from practice in order to make the goodwill saleable. They may make what subsequent use of it they please, provided they do not make use of the ex-partner's name. It is, however, always open to partners to agree beforehand that the goodwill shall have a saleable value, and in any event if the goodwill has actually been sold by

anyone in a position of trust the proceeds can be successfully claimed by anyone who has a just right to them.

For instance, in *Smale v. Graves* (1850) the widow of a dentist was made executrix of his will. She sold the goodwill and an introduction for £500, which she claimed to keep as arising from her personal influence with the patients. The court held that some, at any rate, of this money belonged to the estate.

In *Corbin v. Stewart* (1911) the widow of a medical man, who had not taken out letters of administration and therefore was not acting on behalf of the estate, sold the practice. She used those words in her receipt for part of the purchase money. Her purchaser defaulted and she sued for the balance. Mr. Justice Scrutton, as he then was, considered that she was entitled to sell the right to carry on business in the house, which was her own, but if she was selling the right to say "I am Dr. C's successor" he was inclined to think that part at any rate of the proceeds of the sale of this right belonged to the estate.

COVENANTS NOT TO PRACTISE

The value of the connexion to a purchaser will therefore depend very largely upon whether the original practitioner, or any of the members of a dissolved partnership, continue to practise in the neighbourhood. When a partnership is dissolved the law will not restrain any of the ex-partners from continuing to practise. A partner who has been expelled or who has withdrawn from the partnership and has been repaid his share of the capital will not, unless he has entered into an agreement to the contrary, be restrained from carrying on business on his own account. It follows that when a doctor buys a practice from a retiring colleague, or a partner leaves the partnership, or an assistant or locum tenens finishes his term of service, the value of the connexion will be seriously depreciated if the outgoing practitioner remains in the district and continues to practise, for the patients who have been consulting him will probably continue to do so. For this reason every agreement to purchase a practice, every partnership agreement, and every contract with an assistant or locum tenens should contain a legally binding clause restraining the outgoing party from continuing practice near by. The clause must be drafted by a solicitor with special experience, or the chances are that it will be quite worthless. The fundamental fact about such covenants is that the law originally refused to enforce them at all, holding that they were contrary to public policy, and even now the courts insist that the outgoing practitioner shall not be restricted any more closely than will secure the legitimate interests of those who are continuing to practise.

To make an agreement in restraint of trade valid two conditions must be satisfied: (1) the party who is to be restricted must receive some benefit by way of consideration (something valuable, that is, in return for the freedom he is renouncing); and (2) he must not be restricted more than is reasonably necessary, at the time of making the contract, to ensure that the party who gives the consideration gets the freedom from competition for which he is paying. The mere fact that the doctor is employing the assistant is considered a sufficient benefit to the assistant to constitute consideration for a restrictive covenant (cf. *Davis v. Mason*). The restriction, to be reasonable, must obviously be limited in space, for it will not hurt the buyer of a practice if the seller goes and practises a hundred miles away. It can, however, still be reasonable even if it is unlimited in time, for it protects (at least in England) not only the buyer himself but also anyone to whom he sells, assigns, or bequeaths the practice, and is, in fact, an asset—part of the goodwill. A medical man (at least in England) is still bound by such a covenant even if the other party or his successors have ceased to practise, for the reasonableness of the restriction is determined at the time it was made, and nothing that happens later can affect it.

SIZE OF RESTRICTED AREAS

The size of the area within which the buyer can reasonably demand to be protected varies according to the nature of the practice. The courts have upheld agreements not to practise within ten miles of Thetford and of Newton (Montgomery)—small country towns—and even within

* The first of these articles, by a legal correspondent, appeared on June 9th, 1934 (p. 1053), the second on June 23rd (p. 1145), the third on July 7th (p. 42), the fourth on July 21st (p. 141), the fifth on September 22nd (p. 574), and the sixth on October 6th (p. 669).

twenty miles of Aylesbury. This last case was heard as long ago as 1818, and such a condition would presumably be equally valid to-day, when distances are so much shorter. In London, distances of two and a half and three miles have been held reasonable (*Atkins v. Kinnier, infra*). An agreement not to practise as a surgeon-dentist in London has been held reasonable. On the other hand, when a dentist agreed not to practise within 100 miles of York, the condition was held to be unnecessarily wide for the protection of the other party to the agreement (*Horner v. Graves, 1831*). Unless the method of measurement is stated, the distance is measured "as the crow flies."

The peculiar danger of these covenants is that if by some mistake the area within which an outgoing practitioner binds himself not to practise is too wide, the whole restriction is invalid and the outgoing practitioner is at liberty to practise anywhere. Suppose an assistant to a Halifax doctor agreed not to practise in the West Riding of Yorkshire, and afterwards broke his agreement by practising in Dewsbury; if the courts considered that the West Riding was an unreasonably large area they would hold the restriction invalid as against public policy, and then there would be nothing to prevent the ex-assistant from coming to Halifax and setting up in practice next door to his late principal. The court will not fix a fresh limit. A more frequent source of trouble is faulty framing of the restrictive clause so that it does not entirely prevent the seller, ex-partner, assistant, or locum-tenent from competing. One of the commonest errors of drafting is to forbid the seller to "set up in practice" within a certain radius. If the buyer, under this condition, goes out one morning and finds the ex-owner of the practice calling on some of his old patients at their invitation he has no redress. In order to be safe the restraining cause must prohibit the seller, etc., from doing any act at all in the capacity of a registered medical practitioner within a given reasonable area for a given time. One firm of solicitors with a large medical connexion advises, in London agreements, a double restriction: the outgoing party agrees not to set up in practice, or to practise, within a given small radius—usually one mile—and also that he will not profitably attend upon, advise, or prescribe for a patient who was previously a patient of the practice within a much wider radius, usually twenty miles. The small radius, while legally unobjectionable, gives ample protection against competition for future patients, and the large radius is obviously reasonable for the specific protection of the existing practice.

The words "practising the profession of a medical man" will probably cover every kind of competing activity.

Two medical men, on dissolving partnership, drew a line on a map and agreed not to "exercise or carry on the practice, profession, or business of physician, surgeon, or apothecary at any place within the boundaries of the partnership practice," north and south of the line respectively. One of them attended patients at their own residences on the wrong side of the line and the other sued him. Counsel argued that "practising" in an area meant opening a surgery or having consulting rooms in it, but the court held that the doctor practised his profession every time he attended a patient, and that the patient's house was a "place" within the meaning of the restraining clause.

When a practitioner binds himself not to practise within given limits, a condition that he shall also not live within certain limits is reasonable if it is connected with the covenant not to practise, and is necessary to protect the interests of the other party.

In *Atkins v. Kinnier (1850)* a surgeon, K, entered into partnership with another, A, for three years, and promised that at the end of that time he would not practise or reside within two and a half miles of No. 28, Dorset Crescent, "measuring by the usual streets or public ways of approach thereto," and that if he should break this condition he would pay A £1,000. After the end of three years A sued K on the grounds that his house in Southwark was within two and a half miles of 28, Dorset Crescent. At the trial it appeared that K's house was more than two and a half miles away if the distance was measured by the public thoroughfare most frequented by carriages, but if measured by another public thoroughfare along which carriages seldom passed the distance was a few feet under two and a half miles. There was no evidence that K had done A any damage whatever by living

where he did, but the court found that the contract was broken and ordered K to pay the £1,000. The Exchequer Chamber—corresponding in those days to the Court of Appeal—supported the judge in holding that the condition that K should not reside within two and a half miles was not unreasonable, as a person might reasonably guard against a harmless act in order to prevent an injurious one which might easily follow from it. As the covenant not to practise was legal and binding, and the covenant not to reside was connected with it, this was legal and binding also.

The court has also held reasonable a condition that the retiring practitioner shall not let his house to a medical man. When a retiring practitioner binds himself not to carry on medical practice he is also bound not to act as assistant to a person who does so (*Palmer v. Mallet, 1887*).

RESTRICTIVE COVENANTS IN SCOTLAND

In Scotland the courts have sometimes regarded a restrictive covenant as a purely personal agreement which is not assignable to a successor. In *Rodger v. Herbertson (1909)* H sold his practice to A and agreed that A, his heirs, executors, and successors should have the exclusive right to the practice and the goodwill, and that he himself would cease to practise in the neighbourhood. A assigned the practice and the agreement to R, but when R brought an action to prevent H from practising in the neighbourhood the Court of Sessions held that the contract was personal and intransmissible, and that the term "successor" had no meaning. In this case, however, the court found that certain terms of the contract disclosed *delectus personae* (an exclusive personal reference) as regards the purchaser A, so as to suggest that the agreement was binding on H only with respect to A. Lord Dunedin, the President of the Court, expressly stated that there was no general rule, and that each case must depend upon its own terms and on the just construction of the bargain between the parties. Lord Wark, commenting on this case in an opinion delivered in *Cunningham v. Forsyth (1933)*, dissented from the dictum of Lord Kinnear that in a medical practice there is nothing to assign but a personal goodwill, and that this can hardly be assigned except on considerations personal to the assignee. Although, he said, a medical man may sell his practice only to a person in whom he has confidence, and show by the terms of the contract that he has done so, yet in *Cunningham v. Forsyth* the practice was sold to the first comer by the representative of a doctor under legal disability. It was, he said, a little difficult to see why a restrictive covenant binding the doctor's son not to compete with this first comer should not be transmissible to any practitioner to whom the first comer should sell the practice. There did not, in fact, seem to be any element of *delectus personae* about the transaction. The position is probably, therefore, that even in Scotland a doctor selling a practice to a colleague can, if he makes it quite clear in the agreement that he is doing so, legally bind himself not to compete with any successor of that colleague. Friendly societies and other bodies sometimes insist that their medical officer shall bind himself not to practise in the neighbourhood after his engagement with them is ended. Such covenants have been upheld by the courts.

The courts accept the ordinary covenant not to practise afterwards as a necessary part of every agreement between two doctors who wish to work together, but as soon as two competing doctors try to make a similar arrangement they reject it as contrary to public policy.

Collins v. Locke (1879) concerned stevedores, not doctors, but the same principle would probably apply to medical practice. Four stevedores in Melbourne made a kind of "ring." They agreed to divide the stevedoring business of the port on the footing that each one should do the work on a certain list of shipping firms; if one took a job from a firm "belonging" to another of his colleagues he should compensate that colleague; and if at any time one could not get a particular job from one of his own firms, none of his colleagues should take it. The Privy Council held that the condition by which a party who did work allotted to another should compensate him was fair and reasonable, because each party in turn might benefit by it and the merchant interested in the ship could have his work done by the party whom he wished to do it. The court would not, however, enforce the other clause

—that which provided that if one party was not given the work, none of the parties should take it. This clause, it said, restrained three out of the four parties without giving any of them any profit or benefit to compensate for the restriction, which was also detrimental to the public because it deprived merchants of the services of any of the parties unless they employed a particular one, against whom they might have a perfectly reasonable objection. Their Lordships said that the clause was entirely beyond anything which the legitimate interests of the parties required.

It is therefore practically certain that if two doctors who lived in the same district made an agreement by which each should take certain patients and that neither should attend a patient belonging to the other, the courts would refuse to enforce their bargain. An agreement to allot certain streets or villages to one doctor exclusively would probably be open to the same objection. The courts are very jealous of the public interest in enforcing any agreement in restraint of trade or practice. If, however, a number of doctors agree that, whichever of them does the work, certain doctors shall receive the fees from patients in certain districts, the bargain would be held good at law, because each of the parties would stand to benefit in turn and the agreement would not in any way restrict the services available to the public.

LIQUIDATED DAMAGES

The condition by which a doctor agrees not to practise within a certain area generally includes a covenant that, if he does practise within that area, he shall pay a stipulated sum of money as "liquidated damages." This means that the parties agree that if the covenant is broken this sum shall represent the damage which the owner of the practice has suffered. If the clause expresses that the offender shall pay a certain sum as a penalty for breaking the agreement, then the sum is a penalty and the aggrieved practitioner can only recover a sum equal to the damage he has actually suffered. The courts will not necessarily, whatever the wording of the agreement, award such a sum either as liquidated damages or as a penalty, but will take all the circumstances into consideration. The decisions to be found in the reports suggest that the sum named will only be treated as liquidated damages if it represents a genuine estimate of the damage which the owner of the practice is likely to suffer if the outgoing doctor remains in the neighbourhood. If the sum is obviously disproportionate, the court will not make the offender pay it all; if the sum seems fairly proportionate, it probably will. The aggrieved practitioner can ask the court either to grant an injunction preventing the outgoing doctor from breaking his restrictive covenant or to award damages for the breach, but not both. A practitioner who succeeds in obtaining an injunction will not be allowed to sue afterwards for liquidated damages, and if he is granted damages the outgoing doctor will be perfectly at liberty to practise in the district as long as he likes. The owner can, however, sue both for an injunction and for unliquidated damages—that is, the actual amount of damage that he can persuade the court he has suffered. A doctor who has agreed not to practise on pain of liquidated damages cannot simply offer the amount of the damages and set up in practice.

If the owner of a practice suddenly discovers that one of his old assistants or ex-partners has started to practise in the neighbourhood in defiance of his agreement not to do so, he should lose no time in instructing his solicitor to apply for an injunction. The court will, if he makes out a good case, grant an interim injunction without hearing the other side, and this will protect the practice until the case is tried or for a definite time fixed by the court. If the offender has really infringed the covenant, the court will not refuse an injunction merely because the actual damage has so far been trifling. It is dangerous to delay in these cases, for courts of equity are apt to take the view that if a suitor does not ask for their help in reasonable time he cannot be in any great need of it. The injunction is a most effective remedy, because if the offender disobeys it he can be promptly imprisoned. It is a very different matter from trying to get damages out of an evasive debtor.

Medical News

Lord Moynihan will open the extension of the Samaritan Free Hospital for Women, Marylebone Road, London, N.W., on Tuesday, November 13th, at 3 p.m. It is twenty-seven years on November 23rd since Sir Frederick Treves formally opened the new operating theatre, and referred to the perfecting of the methods of certain operations particularly associated with the Samaritan Free Hospital and Sir Spencer Wells.

On Monday, November 5th, a banquet will be held at the Mansion House in support of the appeal of St. Bartholomew's Hospital Medical College for funds for the purchase and equipment of the site and buildings in Charterhouse Square acquired last year. The Lord Mayor, in a special appeal to the City of London, explains that £65,000 is needed to pay off the balance of the purchase price, £40,000 to alter and equip the existing buildings formerly occupied by Merchant Taylors' School, and £30,000 to build and equip a residential hostel for students. The College authorities have already raised £65,000, and they own a building which it is hoped to sell for £20,000. The new College must be ready for occupation before the opening of the winter session 1935-6. H.R.H. the Prince of Wales, President of St. Bartholomew's, has given his personal support to the launching of this appeal.

A reception will be held at the Royal Society of Medicine on Thursday, November 8th, at 8.30 p.m., when Fellows and their friends will be received in the library by the President and Mrs. Robert Hutchison. At 9.15 p.m. an address (in English) will be given by Professor Arturo Castiglioni, entitled "The Ancient University of Padua and its English Scholars." Admission will be by ticket only.

The annual dinner of the Leeds School of Medicine will be held at Queen's Hotel, Leeds, on Thursday, November 15th. Particulars may be obtained from the secretaries.

The Buckston Browne annual dinner of Fellows and Members of the Royal College of Surgeons of England will be held in the College, Lincoln's Inn Fields, on Thursday, November 8th, at 8 p.m. This dinner, provided through an endowment by Sir G. Buckston Browne, F.R.C.S., has been held regularly since 1928. Those present usually number about a hundred, and at least half of the guests are members of the College.

An address, on "Sir James Paget at Home," will be given by Bishop H. L. Paget on Friday, October 26th, at 8.45 p.m., at the Princess Elizabeth of York Children's Hospital, Shadwell, E.1. Professor G. Grey Turner will occupy the chair. Admission free, without ticket.

After the meeting of the Cambridge Medical Society on Friday afternoon, October 26th, at Addenbrooke's Hospital, Dr. G. S. Haynes will unveil the Arthur Cooke Memorial Plaque. By arrangement with the Cambridge and Huntingdon Branch of the British Medical Association, all members of the Branch are entitled to attend the meetings of the Cambridge Medical Society, which count as clinical meetings of the Association.

A meeting of the Medico-Legal Society will be held at 11, Chandos Street, W., on Thursday, October 25th, at 8.30 p.m., when a paper will be read by Dr. Ainsworth Mitchell on "The Use of Invisible Rays in Criminology," followed by a discussion.

A meeting of the St. John's Hospital Dermatological Society will be held at St. John's Hospital, 49, Leicester Square, W.C., on Wednesday, October 24th, at 4.15 p.m., when clinical cases will be shown.

A course of three lectures on "Forty Years of Gynaecological Endocrinology" will be given by Professor Ludwig Fraenkel, late director of the Women's Clinic in the University of Breslau, at University College Hospital Medical School, University Street, W.C., on October 31st and November 2nd and 5th, at 5.30 p.m. Professor F. J. Browne will take the chair at the first lecture. Admission free, without ticket.

A course of eight lectures on "Psychology and Modern Problems" will be given at the Institute of Medical Psychology, Malet Place, W.C., on Tuesdays from October 23rd to December 11th, at 6 p.m., with the exception of the lecture on October 30th, which will commence at 5.45 p.m. The fee for the course is £1 ls., and tickets may be obtained in advance from the honorary lecture secretary; tickets for single lectures, obtainable at the door, are 5s. each.

The programme for the ensuing session of the Eugenics Society has now been published. On October 30th Professor H. Muckermann will discuss "The Eugenic Movement in Germany"; on November 20th Mr. Herbert Brewer "Eutelenesis"; and on December 18th Dr. Shepherd Dawson "Disease and Intelligence." The meetings will be held in the rooms of the Linnean Society, Burlington House, Piccadilly, at 5.15 p.m., with Sir Humphry Rolleston in the chair; tea at 4.45. All interested in the subjects mentioned are invited to attend.

A post-graduate course on diseases of children will be held at the Great Ormond Street Hospital, W.C., from October 22nd to November 4th, from 10 a.m. to 1 p.m. and 2 p.m. to 4 p.m.; Saturdays 10 a.m. to 1 p.m. The course, the fee for which is £6 6s., will consist of fifty clinical lectures and demonstrations, and six laboratory demonstrations. Applications to take the whole course, or any part thereof, to the secretary of the hospital.

The Fellowship of Medicine (1, Wimpole Street, W.) announces that lecture-demonstrations will be given at 11, Chandos Street, W., at 2.30 p.m. on October 23rd and 30th. The first lecture in the series, on diet and dietetics, will be given at 11, Chandos Street, on October 24th, at 8.30 p.m., by Professor R. J. S. McDowall. A week-end course in diseases of the chest will be held at the Hospital for Consumption, Brompton, on October 27th and 28th. Other forthcoming courses include neurology, at the West End Hospital for Nervous Diseases, October 29th to November 3rd; obstetrics, at the City of London Maternity Hospital, November 3rd and 4th; medicine, surgery, and gynaecology, at the Royal Waterloo Hospital, November 5th to 24th; diseases of the chest, at the Victoria Park Hospital, November 5th to 10th; urology, at St. Peter's Hospital, November 5th to 17th. Courses of instruction, clinics, etc., arranged by the Fellowship are open only to members.

The Italian Congress of Industrial Medicine, which, as stated in our issue of October 13th (p. 705), was to have been held at Turin from October 20th to 22nd, has been postponed to the 25th to 27th.

The fifth Rumanian Congress of Surgery will be held at Bucarest during the first ten days of November under the presidency of Professor I. Bacalesco, when the following subjects, among others, will be discussed: surgery of cholelithiasis; surgical treatment of uterine prolapse; osteosynthesis; genital actinomycosis; and surgical treatment of facial paralysis. Further information can be obtained from Dr. J. Jianu, rue Campineanu 62, Bucarest.

The annual general meeting of the Guild of St. Luke, St. Cosmas, and St. Damian will be held in the Committee Room, Cathedral Hall, Archbishop's House, by permission of the Cardinal, on Sunday, October 21st, immediately after the High Mass at Westminster Cathedral, which will be celebrated at 10.30 a.m. Front seats will be reserved on the Epistle side.

On October 12th Mrs. Charles H. Marshall and Mrs. E. M. Field of New York attended the naming of the "Josephine B. Marshall" pathological laboratory at the West End Hospital for Nervous Diseases. The Bishop of Willesden performed the ceremony, and the Earl of Harewood presided. The late Mrs. J. Marshall was a great benefactress of the hospital, and for ten years, until her death in 1933, she was a member of the committee of management. Mr. and Mrs. Charles Marshall and Mrs. Field gave £3,200 to enable the laboratory to be named after her.

Under the auspices of the Standing Conference of Metropolitan Borough Tuberculosis Care Committees an

exhibition and sale of work made by students attending handicraft classes at tuberculosis dispensaries in London will be held next week at Carpenters' Hall, Throgmorton Avenue, E.C. There will be two opening ceremonies, the first on Wednesday, October 24th, at 3.30 p.m., by the Lord Mayor, and the second on the following day at the same hour by Lord Snell, chairman of the London County Council, after which Sir Henry Gauvain will give an address. Tea will be served during both afternoons (price 1s.), and working demonstrations will be given. Invitations and further particulars may be had from the honorary secretary, Mrs. William Brand, "Pembury," The Drive, Rickmansworth, Herts.

Rural housing in Wales and tuberculosis in cattle will be discussed at a sessional meeting of the Royal Sanitary Institute in the Pier Pavilion, Colwyn Bay, on Friday, October 26th.

In the year ending August 4th, 1934, in eighty-six large towns in the United States, 23.3 persons per 100,000 inhabitants were killed by motor accidents, as compared with 21.1 persons in the previous year.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshuegh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Hospital Wards

Dr. SIDNEY CLARKE (St. Albans) writes: There is a tendency for architects at present to build hospital wards with beds parallel to the windows in place of the usual head to wall. Is this more costly, and does the arrangement lead to increased work? Some sisters are said to view the system with little favour. Would anyone, please, who is familiar with such wards give any information as to the advantages and disadvantages of such arrangements?

Chronic Bone Sinus

Dr. CLEMENT BELCHER (Birmingham) writes with reference to the inquiry by "A.B.C." (September 29th, p. 617): With a deep sinus of such long standing it is questionable if closure would be in the interests of the elderly patient, there being the probability of dead bone for which the sinus gives drainage. I have a similar case, but this is a tuberculous osteitis, not a staphylococcus infection, as is usual, I believe, in acute osteomyelitis cases. This patient has been under my care for forty-five years, and for the last forty has had a bone sinus. In 1890 his right foot was amputated for a tuberculous ankle-joint which troubled him for five years. He then developed a focus in his right elbow, but never would he have another operation. During all this long period he had had treatment every week, first as a "club," then as a panel patient. His

treatment consists of light dressings soaked in boric acid lotion with zinc sulphate and ammon. picrate solution; this has kept the elbow-joint useful. I have removed on several occasions a small sequestrum, but he has carried on his employment as a leather worker all these years, and is still at work at the age of 69.

Income Tax

Cost of Assistant's Board, etc.

"SRS" has claimed £150 per annum as the cost of the board and lodging of his indoor assistant. The inspector points out that the cost of a surgery maid and one-half of the rent, rates, and light and heat are already claimed and allowed as professional expenses.

Though much must depend on the facts of the particular case it does seem that there is not much of the element of "lodging" to be claimed for by "Spes," seeing that it has to be covered by the "lodger's" share of one-half of the rent, etc.—the rent and rates not already allowed amount to £56 per year only. In the circumstances we suggest that a personal visit to the inspector's office might lead to a reasonable compromise.

Income from Dominions

"A. R." is resident in one of the Dominions, and has a private income on which he pays tax there of about £120 per annum. What would he pay if he resided in England?

Assuming "A. R." to be married, but not entitled to "child" or other special allowances, his tax here would be:

	£	s.	d.
On the first £150	nil
On the next £175 at 2s. 3d. in the £	...	19	13 9
On the balance of £675 at 4s. 6d. in the £	...	151	17 6
	£171	11	3

Less Dominion income tax relief, which in the circumstances would represent apparently about half the above amount, leaving "A. R." in the position of paying £120 plus, say, £85 = £205, less any relief he might obtain from the Dominion authorities.

Employment of Wife

"J. G." explains that he has "paid his wife £25 a quarter for years," and "the work she does is worth at least £45 a year," which is all he claimed. The inspector of taxes has refused the claim on the authority of a decision in the case of Thomson v. Bruce.

The allowance of £45 in respect of the earned income of the wife presupposes that the wife's earnings have been assessed. "J. G." does not state whether he returned his wife's "income" for assessment. That was one of the points in the case cited. Another was that accounts had been lodged which did not show the wife's wages as paid out of the business receipts. The question is really one of fact—that is, it is for "J. G." to prove (a) that he did pay wages to his wife for the work she did in the practice, and (b) that he has been assessed in respect of her earnings.

LETTERS, NOTES, ETC.

The G.P.'s Nightmare

To those who may have had similar dreams, this one of Dr. J. Vergely's may bring the comfort of a fellow-sufferer. We translate it from the *Journal de Médecine de Bordeaux*, 1934, xxv, 681.

I have had a frightful dream. I distinctly saw coming towards me a man with his flesh flayed and large tears running from his eyes. In spite of this horrible mutilation, he walked and spoke without difficulty. When he reached the place where I was, he stopped and made a sign that he wished to speak with me. "Who are you?" I asked. "Who am I?" he replied. "I am the last survivor of a disappearing race, one which, when I am gone, will become completely extinct. . . . I am a practitioner of general medicine. No doubt you are surprised to see me in such a sorry state, but it is all the fault of those specialists. They have taken everything from me, even my skin, bit by bit. As you see, they have left only my eyes, so that I can weep. Ah! how magnificent was the life I used to lead, and who would have said that I

should come to this? But, let me tell you, my condition was not always so deplorable. When I began the practice of medicine I was, if not exactly rich, at least properly clothed; and I tried my best to care for suffering humanity. Up to the time of the war things went on in much the same way. True there were already specialists. Besides the surgeons and, within their ranks, the genito-urinary surgeon, the gynaecologist, and the orthopaedic surgeon, there were also the obstetrician, the dermatologist, the oto-rhino-laryngologist, the dentists, the radiologists. But that was almost all, and these specialties seemed to us to be justifiable. But since the war! Ah! my good sir, there have sprung up the foot specialists who have taken our feet from us, the cardiologist the heart, and the tuberculosis experts who, under the guise of this disease, have stolen all the maladies of the lung. I will not refer to the paediatric physicians, more wildly specialized than before, nor to the neurologists or the psychiatrists, who speak a language which becomes more and more esoteric. Then there are the specialists for rheumatism, lymphatism, and much else besides; and the last thing I heard of was that there were specialists for diseases of the vessels and for endocrine disorders. I tell you truly that they have taken everything from me, bit by bit, and have left me only my eyes to weep with. Ah! he cried, striking his chest, "I will go and specialize in unknown diseases."

Treatment of Trichophyton Infection

"M.D." writes: The difficulty in effecting a cure of trichophyton infection of the fourth interdigital spaces of the feet has recently been alluded to. The experiences of a sufferer may be of assistance. For several years I have persevered with a number of treatments, often for several months each. All have failed to produce improvement with one exception. Cignolin (Bayer) grains x in benzol 3i is the exception. A solution of silver nitrate, x rays (1/4 pastille on one occasion, 1/2 pastille on another), Castellani's fuchsine paint, chrysarobin ointment (8 per cent.) have all proved completely ineffective. Whitfield's ointment, containing salicylic acid grains xx and benzoic acid grains xxv to an ounce, applied nightly on pledgets of cotton-wool, produced almost intolerable smarting and a marked extension of the disease, so that the whole interdigital skin, up to the tips of the affected toes, became white and infected. Cignolin alone has produced improvement; but of cure I begin to despair.

Lethal Noises

Dr. W. J. BURNS SELKIRK (Birmingham) writes: In reading Dr. Dan McKenzie's paper on "Noise and Health," in the *Journal* of October 6th (p. 636), I recollected two curious instances of the effect of noise given in Hudson's book, *A Hind in Richmond Park*. (1) A baby died as a result of an explosive sneeze by another person in the room. (2) A man had so loud a voice that when, in temporary forgetfulness, he shouted loudly at his ox the ox fell dead. I think the sudden shriek of the whistle of a passing railway engine can cause fits of terror in a baby for months afterwards.

Medical Golf

The autumn meeting of the Sussex Medical and Dental Golfing Society was held on the course of the Dyke Golf Club, Brighton, on September 30th, when twenty-eight members were present. The weather was fine and warm, although there was a strong wind. The morning round, for the captain's prize (presented by Dr. A. E. Drynan), against bogey resulted in a win for Dr. H. Butcher with a score of 2 up; M. W. Pilcher was second (1 up), and the prize for the sealed holes was won by Dr. J. M. Anderson. In the afternoon the competition took the form of a four-ball foursomes against bogey, resulting in a win for Drs. Bond and Devlin (4 up), the runners-up being Drs. J. Thwaites and J. K. Raymond, who tied with Drs. G. Thwaites and A. E. Drynan, with 2 up.

George Newnes Limited announce the publication, in fortnightly parts, of a popular work entitled *An Outline of Modern Belief*, by J. W. N. Sullivan and Walter Grierson.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 50, 51, 54, and 55 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum-tenencies at pages 52 and 53.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 212.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, OCTOBER 27th, 1934

BAD SURGICAL RISKS*

BY

G. GORDON-TAYLOR, O.B.E., M.A., M.S., B.Sc., F.R.C.S.

SURGEON TO THE MIDDLESEX HOSPITAL, ETC.

Apart from the technical competence of the operator, the organization of his theatre, and the environment in which he works, there are many factors which combine to determine the success or failure of a surgical operation, and which contribute towards promoting a glorious result or compassing a fatal ending. The title of the subject for this discussion might appear literally to indicate surgical undertakings which, by reason of their magnitude, by reason of the condition of the patient, or possibly because of both these causes co-operating, seem fraught with grave but justifiable hazard; or the reader perusing the wording of this theme might contemplate a morning spent on listening to a veritable catalogue of perils to which patients have been quite unwarrantably exposed by operators, whose conduct is tacitly implied to have been reprehensible in this respect. The parlance of insurance has, however, invested the term "bad surgical risk" with a rather different connotation: it is the operated, and not the operation, that is envisaged, and the *bad surgical risk* has been defined by Basil Rooke¹ as "a type of patient whose prospect of recovery from active surgical treatment of his condition falls much below the average."

It is not, therefore, intended to discuss in these columns surgical enterprises formidable in magnitude and no less forbidding in their prospective mortality, such as the total extirpation of the thoracic oesophagus for cancer and its reconstitution by some form of oesophagoplasty, a surgical triumph gained in this country only by Grey Turner² of Newcastle in that *annus mirabilis* of oesophageal surgery, 1933, and more recently abroad by Gohrandt of Berlin.³ We are not to consider the ablation of large hepatic tumours, whether these be primary hepatic adenomata or the direct extension of a colonic cancer. Interpelvi-abdominal amputations⁴ claim no attention in this discussion, although they are still associated with an operative anxiety sufficient to designate their performance as a risky procedure. Dramatic and heroic extractions of emboli from the pulmonary artery, although bad surgical risks in the literal sense, are to make no claim on our notice, nor are the marvellous encroachments of war surgeons into operative fields hitherto unexplored, than which there has been no greater hazard and no more glorious attainment than Pierre Duval's extraction of a bullet from the intrapericardiac portion of the inferior vena cava.⁶ In this discussion it is upon the patient himself rather than upon the operation that attention is to be focused.

Various causal agencies are operative in determining a patient a "bad surgical risk": (a) aetiological factors—for example, race, sex, heredity, age, etc.; (b) bodily conformation—fat, colour of hair, etc.; (c) previous

habits and mode of life; (d) antecedent or intercurrent disease, and the state of the cardiovascular, respiratory, urinary, and nervous system; (e) the psychology, etc., of the patient; (f) the pathological condition for which surgery is contemplated, the severity of that condition, and the existence of secondary phenomena affecting the sufferer prejudicially; and (g) the type of operation proposed.

This discussion would assuredly be judged incomplete, and would fail in its object, if one were content with delineating and portraying these "bad surgical risks," and did not adumbrate the therapeutic measures whereby these patients might be made safe, or safer, for surgery.

General Aetiological Factors

Race.—It would be difficult to controvert the accepted view that members of the Jewish faith are notoriously "bad surgical risks"; and in the case of operation the simplest measures are to be preferred: safety must be put before thoroughness and the highest efficiency. It is easier for "a camel to go through the eye of a needle" than for a Jew to recover from an abdomino-perineal excision of the rectum; a perineal ablation must suffice. Moreover, although a Jew may recover from a gastrectomy for ulcer, it is rare for recovery to take place when the pathological condition demanding an extensive removal of the stomach is a malignant growth. I have, nevertheless, a Jewish patient alive five years after a gastro-colic resection for a carcinoma involving the stomach and the whole of the right side of the colon; this is, however, a very exceptional case, which goes to "prove the rule." The Welsh and Irish[†] have also been impugned as relatively bad risks. The Chinese stand operation well; but my experience of war surgery among those who came "from India's coral strand" convinced me that they were extremely "bad risks."

Mr. Green-Armytage⁷ kindly informs me that the operative risk in natives is related in no small degree to such considerations as blood count, calcium index, blood pressure, which are all lower than those of the "Westerner"; their diet, whether they be meat-eaters or vegetarians, is always defective in vitamin A, with the result that their resistance to infection is below normal, and a merely moderate degree of infection of thorax or abdomen proves fatal. Considerations of diet may also be responsible for the frequency of post-operative ileus after abdominal operations, and for the alarming acetonaemia which may supervene after surgery. On the other hand, the increasing desire of the native to get out of bed at the earliest moment after operation, and the good

* Read in opening a discussion in the Section of Surgery at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

† A lengthy experience of surgery behind the 16th South Irish Division during the war does not confirm but rather refutes this opinion.

musculature of the abdomen, make post-operative thrombosis rare.

Sex.—It is well known that certain operations, such as the extirpation of the rectum by the combined method, are better borne by women than by men, but on the other hand I am confident that gastrectomy is an operation far more frequently followed by anaemia in females than in men,⁸ and therefore to be performed in the former sex more reluctantly. Operations are badly borne during menstruation, pregnancy, and parturition. The sinister effect of the menstrual period upon a radical breast operation is perhaps not sufficiently well known; such an undertaking at that epoch may well prove calamitous.

Heredity.—A long-lived ancestry is a precious possession and an asset of no mean worth, if surgery be contemplated. There are at present no means of altering for the better the proclivity of this or that race to react badly to surgery; we cannot in the twinkling of an eye transform ancestral inheritance or racial characteristics, any more than can "the leopard change his spots or the Ethiopian his skin."

Age.—It is obvious that surgery must be safest during those years when the individual is in his prime, and that operations performed at the extremes of life must carry with them a greater risk than those carried out during the intermediate decades. Nevertheless, it is a remarkable fact that surgery undertaken in the first three months of infant life by skilled and experienced operators is extremely well borne.

Mr. Tyrrell-Gray,⁹ whose considered opinion, based on a vast experience of children's surgery, is an authoritative one, has courteously informed me of the

"absolute safety of Ramstedt's operation for pyloric stenosis; the absolute safety of herniotomy, even double herniotomy, in these early months, if this operation has to be done on account of large size, obstruction, or strangulation, or because it cannot be controlled by any form of truss; likewise the safety of hare-lip operations (although he himself prefers waiting)."

The great anxieties naturally associated with emergency operations during the first few days of life are concerned not so much with the paucity of the hours of separate extrauterine existence as with the actual pathological condition demanding surgery. Fortunately, congenital intestinal atresia is rare, as is also congenital volvulus but all cases, except the simplest malformation of the hindgut, are extremely "bad surgical risks." Nevertheless, Mr. Gabriel has successfully closed a colostomy performed for some congenital hindgut malformation as an emergency operation in the first few days of life.¹⁰ Apart from gangrenous changes demanding resection of bowel, the prognosis in intussusception is excellent, despite the fact that 50 per cent. of the cases occur between the fifth and ninth months of infant life. Early diagnosis, prompt surgery, and the method of anaesthesia have all conduced to the attainment of this low mortality. Gas and oxygen would appear to be the anaesthetic of choice in these cases, but in my own hands spinal anaesthesia has given me a mortality of only 2 per cent., my one fatal case being one demanding an excision for gangrene of the bowel. The occasional publication in medical journals of successful cases of intestinal resection for gangrenous intussusception in early infancy bespeaks the fatality of the procedure: the continuity of the bowel must be re-established at all costs; a time-saving but chicken-hearted enterostomy after resection is always fatal in these cases.

The aged are naturally "bad risks" in cases of injury, and where any operation of severity is contemplated. The adage that "a man is as old as his arteries" must be constantly kept in mind if any complicated surgical incursion

is under consideration. In the very old, local anaesthesia is probably the method of choice, and with its aid I have successfully performed a colostomy for a woman of 98 years with a cancerous rectum, who survived a year; and, in the case of a male nonagenarian, I anastomosed the ileum to the pelvic portion of the rectum for a large obstructing carcinoma of the sigmoid; the patient survived two years, and died of uraemia. It is only fair, however, to record that the oldest patient successfully operated on had general anaesthesia administered; she was a woman of 107 years with a strangulated femoral hernia, and was alive a year after without sign of recurrence. I have, under light general and local anaesthesia, resected a carcinoma of the transverse colon in a gentleman of 85, who is alive six years after.

Bodily Conformity

Those whose stature and form are abnormal are "abnormal surgical risks." The microscopical woman of a few stones in weight may finally disappoint the operator just as easily as the giant or the Hercules.

Fat is well known as a surgical handicap, and where there is no necessity for special haste time may be well spent in reducing weight and improving the musculature of the heart and body under the guidance of a skilled physician and the co-operation of a biochemist. Apart from the mechanical difficulties of operation in the obese, the depth of the wound, the friability of the tissues, the less secure ligature of vessels by reason of greasy gloves, the obscuration of the serous coat of the large intestine by enormous appendices epiploicae and the fatty tissue on the bowel, it must be remembered that there is probably the same amount of fat round the heart and in the heart itself; it is this type of person who perhaps appears more prone to thrombosis and embolism, and who certainly resists infection less well than his neighbour of more spare frame. Any operation for a ventral hernia in a fat woman, where much of the contents of the abdomen have been long outside the coelom and are now replaced, is almost always disastrous.

The general condition of tissues is also important. Prolonged confinement to bed tends to produce deterioration of the tissues of the body, a poor cardiac musculature, and a general inability to respond to any severe surgical procedure. On the other hand, confinement to bed for a few days before operation may be a most salutary preliminary measure: this simple measure may make an easy operation of one which promised to be difficult, and less pain is experienced by the patient than if he had had his abdomen opened "the morning after the night before." The auburn-haired, especially children, are liable to occasion anxiety during and after operation, and their scars have a tendency to become keloid in character: a keloid condition resulting from a circumcision is a terrible sequel to the commonest operation in the world.

Habits

It is obvious that those addicted to excess in the matter of alcohol, tobacco, drugs, etc., must be "worse surgical risks" than their fellow creatures. The liability of the alcoholic to develop delirium tremens after operation or injury is well known: the mortality of any post-operative chest complication is far higher, but if he is already the possessor of a cirrhotic liver, the chances of his recovery from any really severe operation are remote.

Antecedent or Intercurrent Disease

This must obviously prejudice the patient's chances of a successful operation, and this is the more true of cases in which disease is latent and unexpected, and when some urgent operation is required. How often has pulmonary

tuberculosis flared up—perhaps disastrously—in a patient making a good recovery from a perforated gastric ulcer. Where the thoracic condition is known beforehand, the use of an appropriate anaesthetic may minimize the risk.

Cardiovascular disease and degeneration must obviously load the balance against the patient: arteriosclerosis and calcification of vessels will obviously be a matter of greater moment in some varieties of operation than in others. When vascular disease is combined with fat in a Jewish patient with a growth in the colon, the surgeon will be prudent who avails himself of the Paul-Mikulicz type of exsection. The co-operation of a good physician—not necessarily a cardiologist—is of great help in the pre-operative treatment of those with a heart and a blood pressure deviating from normality, who are awaiting a severe operation. Sometimes, in spite of cardiovascular degeneration, "bad surgical risks" will recover from very severe surgery, and I have saved a hind-quarter amputation in a man of 63 with marked calcification of all his arteries, demonstrable in radiograms. Again, four years ago I extirpated a cancerous rectum for a patient of 75 years with auricular fibrillation who still survives. Vascular disease carries other risks more remotely connected with the operation, such as cerebral haemorrhage, cerebral thromboses, intraocular haemorrhage, etc., but usually those with a high blood pressure are found to stand operation extremely well. A low blood pressure is a more serious handicap for severe surgery than is hypertension.

The development of post-operative thrombosis and embolism is one of the tragedies of surgery. George Bankoff,¹¹ employing a thyroxine test, was able to group patients into two classes: (a) thyroxine-sensitive, and (b) thyroxine-resistant; he further found that it is only in the thyroxine-resistant cases that thrombosis occurs. He claims that the complication can be prevented by three hypodermic injections of atropine 1/100 grain and ephedrine 1/4 grain; these are commenced on the first day after operation, and repeated on the third and fifth days.

The odds must be desperately against survival from any but the simplest operation in those with Addison's disease*; my only case of appendectomy in such a case died. I have had no personal experience of eucortone in this rare disease, and in an emergency there is little time for premedication.

In diabetes the risks and dangers of surgery are now negligible since insulin and glucose therapy have been employed pre-operatively. The cause of death in fatal cases is senility, not the glycaemic condition. The only anxiety is post-operative vomiting, especially if the patient is unable to take glucose. Renal disease obviously constitutes an added risk: renal breakdown will be referred to when genito-urinary operations are under consideration.

Antecedent infections constitute an added risk in surgical procedure. Those who have suffered from *erysipelas* in the past may develop it again during the aftermath of an operation, and those who have had *tetanus* in connexion with a wound years before may have a recrudescence of the infection if the part be re-operated on; the fresh outburst may indeed prove fatal. I have known an alarming recrudescence of a *pyogenic infection* in the case of a man with a diaphragmatic hernia resulting from an old abdomino-thoracic gunshot wound: the hernia was operated upon by the transthoracic route ten years after his original wound. In these matters the bacteriologist may afford most valuable aid. Those who have recently suffered from some systemic infection, such as pneumonia, influenza, etc., are bad risks. Where opportunity arises, operation should be deferred as long as

possible. The performance of herniotomy soon after a bad cold or an attack of influenza has been followed on more than one occasion by thrombosis and by recurrent embolism, and it is my practice to defer these operations until the summer, especially in the case of those who are approaching, or who have reached, middle age. The syphilitic who has been well treated for his disease usually bears operation well, but the onset of a gastric crisis or some other type of crisis may occasion some anxiety during convalescence. The presence of a syphilitic history will modify the type of operation envisaged. The onset of general paralysis may be precipitated by an accident in those who have had syphilis.

Second operations, following hard on the heels of the primary surgical attack, are apt to be followed by thrombosis of lung or limb; but in these cases the operation is almost always of an urgent character, and the surgeon cannot choose his own time.

Psychological Factors

Any surgeon of experience will have convinced himself that "the psychological undesirables," considered from an operative viewpoint, constitute as numerous and motley a collection as the Gilbertian list in *The Mikado*. That surgeon will be wise who refrains from any operation of convenience upon those who require much persuasion or over-persuasion: he should beware of the apprehensive patient; and he will also regard with anxiety the man with huge piles of books on the tables at each side of his bed; the man with the rapid pulse and the stack of French novels around him; and likewise the individual who is reading his paper upside-down!

An eventful recovery, or worse, may be confidently predicted for those who change their religion the night before an operation, and for the politician or potentate who keeps the theatre waiting while the final lines of his autobiography are completed. These types may well be regarded as "bad risks" before operation, but the appearance of these eccentricities or unusual whims in a patient after surgery are signposts of ominous portent. Unfortunately, this attitude of mental unrest often develops only after an operation, and the operator may be taken unawares. It is commonplace experience that clergymen, doctors, nurses, actors, and those of an artistic temperament are "poor surgical risks": and garrulous loquacity, pre-operative or post-operative, whether it be an individual trait or a transient phenomenon, is a danger signal that should not pass unnoticed: it so often heralds surgical disaster.

Pathological Conditions Demanding Surgery

There are certain anatomical regions of the body which appear to tolerate surgical incursion and attack far better than others; in this respect the gynaecological surgeon is at a great advantage: the invulnerability of the pelvis is a surgical adage. No matter what the pathological condition present, no matter how derelict the patient, a good result may be almost confidently predicted. *The pelvis is indeed the surgeon's fairyland*: there are few or no "bad surgical risks" in this area of the body.

Surgery of Thyrotoxicosis

To my mind the greatest advance in surgery during the last quarter of a century has been the extraordinary increase in the safety of operations for this condition. Whereas operations for this type of case were at one time fraught with grave anxiety and associated with a heavy mortality, save in the hands of a few with great experience and special knowledge of the disease, it has now become one of the safest of the operations of surgery.

* Carl Greene, Walters, etc.,¹² report a successful orchidectomy for tuberculosis in a patient with Addison's disease.

Pre-operative medication with iodine, and the repeated investigation of the basal metabolic rate during the pre-operative period of rest in bed, has made these cases almost safe for surgery. The surgeon has become almost a mere carpenter in the hands of the physician and biochemist, who indicate the exact time for surgery with an accuracy akin to that of the astronomer. The work of our Courtauld Institute of Biochemistry at the Middlesex Hospital has enabled us to reduce the mortality of the operations for toxic goitre to an almost infinitesimal figure: the larger number of cases have been operated upon by my colleague and assistant surgeon R. Vaughan Hudson, but the results of all the cases operated upon by all the surgeons in Middlesex Hospital yield a mortality rate of under 1 per cent. For my own part I prefer regional anaesthesia, but the combined results of eight surgeons, employing almost every variety of anaesthesia, would appear to discount the value of my personal predilection. Increased knowledge has given even those whose goitre operations are not yet to be numbered in thousands rules by which dangerous surgery may be avoided in this class of patient.

Operation is contraindicated and dangerous in the following circumstances: (a) If the patient has been dosed with iodine indiscriminately for months or years previous to seeing the surgeon with a view to operation, at which time the basal metabolic rate is above 40, and tachycardia is present, along with marked loss of weight. (b) If, when put on iodine by the surgeon preparatory to operation, the patient gets clinically worse and the basal metabolic rate rises. (c) If operation is delayed too long after iodine has been prescribed; the iodine loses its action, and the basal metabolic rate rises even on iodine. (d) In the presence of an "acute" infection, such as tonsillitis. (e) If the patient is mauiacal or mental. (f) If the patient shows an idiosyncrasy to iodides, as is seen by coryza, nasal discharge, skin eruption, and bronchitis. These risks can be overcome by the following measures: (a) Only giving iodine immediately prior to operation. (b) Operating only if the response of the patient to iodine is favourable—that is, the basal metabolic rate falls to constant low level. (c) Not operating if iodine makes the patient worse: the iodine should be stopped for about two months and then restarted in an effort to obtain a favourable response: this invariably happens. (d) Operation should not be delayed too long after iodine has been started—that is, more than twenty-eight days. In spite of current belief, the following are not contraindications: (a) heart failure, congestive or anginal; (b) auricular fibrillation or flutter; (c) hypertension; (d) extreme youth or old age.

Surgery of the Tongue and Mouth

Increased knowledge and experience of radium therapy has given us an alternative method of treatment for those who are, on general grounds, or because of the extent of the growth, considered "bad surgical risks." Whatever views may be held as to the best form of treatment for cases of cancer of the anterior half of the tongue, which are "good surgical risks"—and each such case must be considered strictly from every point of view—there can be no doubt that the final results of radium therapy are at least as good as, and probably much better than, those of surgical extirpation, where the growth involves the posterior portion: and the mortality of the procedure is but a fraction of that involved in the more drastic measure.

"Block-dissections" of the neck for the extirpation of the cervical glands are usually well borne even by the aged, but in the case of bad risks, and for recurrence, the various methods of radiation therapy are available.

Surgery of Peptic Ulcer

Ill-advised, ill-timed, or inappropriate surgery may convert into a "bad risk" one which seemed to promise well. There is no single form of operative procedure universally applicable to every case of peptic ulcer. Apart from those general considerations, outlined in the introductory paragraphs, which combine to constitute a patient a "good" or "bad" risk, there is perhaps no factor which so cogently determines in which class the sufferer shall find himself during and after a gastric operation as the judgement of the surgeon under whose care he is placed. By surgical judgement, or the lack of it, the patient's cause may be won or lost.

The immediate result of surgical incursion will be undoubtedly influenced by the particular technique employed: it is manifest that for the patient who is admittedly a bad risk the most simple, the most gentle, the most rapid procedure is the method of election. The position of the ulcer, its size and fixity, any suspicious characters suggestive of malignancy, the results of fractional gastric analysis, are all points worthy of careful consideration in the "good risk" candidate for a gastric operation, or in one whose previously poor and debilitated condition has been improved by preliminary treatment to approximate normality. Although these data, amassed and collected by radiological and biochemical methods, will assuredly influence and determine the type of operation in the "good risk" patient, in the "poor surgical risk" they must not be unduly stressed: a gastro-jejunostomy, or even a jejunostomy, performed under a local anaesthetic may be the wisest procedure, and at worst the patient's condition may be improved and ameliorated, so that more drastic surgery may be considered later, if by any chance symptoms should reappear, or should that full measure of health which surgery can confer not have been attained by the minor procedure.

The dangers of post-operative complications in "the bad surgical risk," as indeed in all those who undergo upper abdominal surgery, may be greatly reduced by the employment of regional and splanchnic anaesthesia: this may be combined with very light general anaesthesia. Light ether, or even ether and chloroform anaesthesia in combination with the methods of infiltration, has, in the last dozen years, practically abolished thoracic complications in my upper abdominal operations. With such a technique the mortality of gastrectomy for ulcer is under 4 per cent.

High spinal anaesthesia, with the great fall of blood pressure induced, has not in my hands been found to help the "bad surgical risk"; but the surgeon will, of course, utilize that technique with which he has made himself familiar, and which has always given him the best results.

Gastric and Duodenal Haemorrhage from Ulcer

A patient with a chronic peptic ulcer may be made a "bad surgical risk" by ill-judged and indiscriminate surgery, but he is already and at once a "bad risk" when he has bled from that chronic ulcer. Furthermore, if such a patient is a "bad surgical risk," he is no less a "bad medical risk," although the truth of this latter statement may not have always been appreciated. The mortality from bleeding among cases of chronic ulcer of the stomach and duodenum treated by non-operative measures at Middlesex Hospital from 1924 to 1933 amounted to 24 per cent.—a percentage mortality almost identical with that obtained by A. M. Coove from the St. Thomas's figures; in the Middlesex Hospital cases a second large haemorrhage produced a mortality rate of 78 per cent., and with each succeeding haemorrhage the risk became greater and,

greater. It would therefore appear that in these cases operation is required before a second haemorrhage takes place, and that for such patients, and at the particular stage in the course of their illness, surgery is the only logical measure of safety. The surgical risk would appear to be least bad, and the moment for intervention most opportune, not longer than forty-eight hours after the bleeding has ceased.

Finsterer of Vienna,¹⁴ however, regards bleeding from a chronic ulcer as an imperative indication to operate at once. Early operation in his hands is associated with an extraordinarily low mortality. After twenty-four to thirty-six hours they become bad surgical risks, and the mortality rapidly rises. My own figures for operations performed for acute haematemesis from 1919 to 1926 show a mortality of 19 per cent., so that the risk is not inconsiderable. Closer co-operation between physician and surgeon will show us which are the cases that should be attacked by surgical intervention; but if surgery be required operation should be performed early under local anaesthesia, and in certain cases a caecostomy may be advantageous.

The possessor of an anastomotic ulcer is a "bad risk," and to quote the words of Garnett Wright,¹⁵ "The Angel of Death is hovering near, and the fluttering of his wings can be almost heard." The patient, worn out with pain, is in many cases little able to stand the prolonged and complicated surgical operation which is required to relieve his symptoms and to prevent a recurrence of his malady. Increasing experience of the operative surgery of this condition, which is in itself becoming more frequently encountered, will doubtless lower its mortality in the hands of those who most frequently have to treat these cases. A gastro-jejunal or a jejunal ulcer may be a severe burden to bear, but an added communication with the colon increases the duration of the operation to cure it, and a complicating haemorrhage makes the risk more desperate than ever.*

Gastric Cancer

All gastric cancers are "bad surgical risks," and I am in the habit of teaching that, whereas a gastrectomy for ulcer will always try to live, a gastrectomy for cancer will always die if he can. Nor am I alone in regarding the condition and its operative surgery as a "bad risk," for Bastianelli,¹⁶ whose enterprise and whose sympathy enable him to resect no less than 44 per cent. of his cases, admits a mortality of 28 per cent. Even excluding three cases of total gastrectomy and twelve stomach-colon resections—which, of course, tended to increase the death rate—his mortality rate from operation was 25.4 per cent.

Finsterer,¹⁷ however, employing local anaesthesia, had only twelve deaths in 202 operations—6 per cent. In the advanced cases where pancreas, colon, or liver are involved, resection carries, of course, a much heavier mortality. In those cases of cancer of the stomach associated with stenosis at the pyloric extremity, protracted vomiting, dehydration, toxæmia, etc., may make a single-stage operation a tax on the patient's resisting and recuperative powers that he is incapable of bearing. In these cases, therefore, a preliminary drainage operation and a subsequent resection may turn the "bad risk" into a "good" one.

According to the condition of the patient, the procedure may take the form of an ordinary anterior or posterior

gastro-jejunostomy and a later resection; or the stomach may be cut across above the growth and an anastomosis performed between the proximal end and the small intestine. The upper end of the distal segment is sutured over, and the suture line reinforced by omentum. The operative technique of the operation is improved and facilitated by a clamp of the von Petz type. It is almost imperative in every case of gastrectomy for cancer to make use of the transfusion of blood.

Surgery of the Spleen.

There are certain forms of splenic pathology where operation is associated with severe risk. The danger of post-operative thrombosis in cases of splenic anaemia with a high initial blood platelet count is perhaps not always sufficiently appreciated: R. E. Kelly¹⁸ of Liverpool has, amongst others, drawn attention to it. The services of a competent haematologist are of the greatest importance when splenectomy is contemplated for this disease. Splenectomy for thrombocytopenia has, in my experience, been a most dramatic and a safe operation, but the mortality has been affirmed to be 80 per cent. when the operation is done in an acute phase. The risk of transfusion in cases of acholuric jaundice is not inconsiderable.

Cancer of the Colon and Rectum

It will naturally depend upon that percentage-mortality which is regarded as fair and justifiable for an operation, to designate the surgical adventure as a "good" or "bad risk." By reason of the operative mortality of colectomy for cancer of the colon, it would seem that most of these cases are to be regarded as "unfavourable risks." S. Strunk,¹⁹ in 1928, while affirming that surgery offers the only cure for malignant disease of the colon, deplored the high mortality of colectomy. "Except for operation in certain serious emergency cases," he wrote, "the mortality following operation for cancer of the colon is perhaps higher than in any other type of intra-abdominal operation."

Grey Turner in 1929²⁰ admitted an operative mortality of 12.28 per cent., but many of his cases were most complicated resections. He appears to think that a mortality of 5 per cent. would represent the acme of surgical judgement and the perfection of operative technique. The mortality of the procedure may be reduced, and the risk improved, by drainage of the bowel, preliminary or simultaneous, the employment of exteriorization methods of the Paul-Mikulicz type, lateral incisions over the growth where possible, the provision for drainage of the abdomen at the site of anastomosis, the employment of blood transfusion, and possibly preliminary immunization. The mortality of operations of the Paul-Mikulicz type in my hands is in the neighbourhood of 1 or 2 per cent., and these should be used more frequently.

In the case of cancer of the rectum there are many types of operation, but the most important factor in the management of the case is the judgement of the surgeon. In forming a judicious estimate of his patient he will take into consideration the age, the sex, and the cardiovascular system; the urinary tract and the bodily configuration of the invalid will also demand attention. A preliminary microscopical section of the tumour may be possible, and may help in forming an opinion as to the malignancy of the particular cancer. The surgeon may utilize the Moots-McKesson test of operability by employing what is termed the "pressure-ratio percentage"; the pulse pressure over the diastolic pressure is calculated in percentages, the normal being about 50 per cent. If the pressure-ratio is high or low there is reason to apprehend danger. If below 25 per cent. or above 75 per cent. the case is inoperable. Close attention to these points and a wise and judicious decision will make a "risk" a good or fair one.

* Mr. A. J. Walton has operated on seventy-nine of these cases, and out of his last twenty cases has had the amazingly low mortality of only one death (*Lancet*, April 28th, 1934). My own results (G. G. T.) are: fifty-four anastomotic ulcers treated by resection, with ten deaths. Excluding ten cases in which there was a communication with the colon, and of which four died, there were six deaths in the remaining forty-four cases—that is, 13.6 per cent. mortality.

The Surgery of the Biliary Tract

In contrast to the extraordinary safety of operations on the gall-bladder the surgery of the common bile duct is associated with a much heavier risk to life. To make these cases of jaundice safer for surgery operation should be deferred until the jaundice begins to subside. Blood transfusion is better than intravenous calcium chloride as a means of diminishing or preventing the tendency to haemorrhage, and is especially valuable where the bilirubin curve tends to rise. It is also important to administer large quantities of water and of glucose before and after operation—by the rectum or by intravenous infusion. In the worst cases of jaundice nothing more than drainage should at first be essayed.

Genito-Urinary Surgery

A candidate for the operation of prostatectomy is a "bad surgical risk" if the operation is performed when the blood urea is over 60 mg. per 100 c.cm.; and if there is evidence of moderate renal impairment, even in spite of a normal blood urea estimation. Eric Riches and Douglas Robertson²¹ regard it as dangerous to operate radically if the urea-clearance test of van Slyke for estimation of renal function is below 60 per cent. of normal, no matter how normal may be the blood-urea estimation.

Secondary nephrectomy for any condition is always an anxious operation, and two or three transfusions and infusions may be required to carry the patient through his convalescence from what may be a carnivorous type of surgery.

Conclusion

It requires no superlative enthusiasm of mine, no unwarranted optimism, to foresee and foretell that, as the "bad surgical risk" of a decade or two ago is now a "normal or good risk," so will the "despairs" of to-day be the "certainties" of the morrow. The craftsmanship of surgery is not yet finished and perfected as an art—fresh techniques will be evolved, fresh avenues of approach will be explored, fresh territories will assuredly be conquered. More accurate and certain knowledge of the causation and cure of disease, and methods and forms of therapy still undreamt of, will in future days cheat and rob Death of those victims that, in this twilight of our surgical wisdom, appear to us now beyond all mortal aid.

RETROVERSION OF THE UTERUS*

BY

S. GORDON LUKER, M.D.CAMB., F.C.O.G.

BOURNEMOUTH

The usual position of the uterus is one of antelexion and anteversion in the middle of the pelvis, the axis of the uterus being very nearly horizontal. When the exact opposite of this occurs the uterus is retroverted and retroflexed. In between these two extremes any position of the uterus may be found. It is usual to describe a uterus as retroverted when the cervix is pointing downwards or forwards and the axis of the body of the uterus is directed backwards. The retroverted uterus is often retroflexed as well.

The normal position of the uterus is maintained by the structures which are attached round the supravaginal portion of the cervix. These are the pelvic fascia, the bases of the broad ligaments, and the utero-sacral ligaments.

There is a wide divergence of opinion as to the symptoms which result from retroversion of the uterus and the treatment required. Some confusion has arisen from grouping all cases together and not separating those of congenital origin from those acquired after pregnancy and labour. It is my intention, therefore, to make as clear as possible the different groups of cases.

Classification

1. The group of those women who are single and have congenital retroversion. It is a fact that many of them are unconscious of the condition and have no symptoms; these, of course, require no treatment. There are others, however, in whom symptoms begin to appear as they get older. This may be due to increase in degree of the condition, with increasing retroflexion, giving rise to venous congestion and symptoms of backache, increasing dysmenorrhoea, pelvic discomfort, or pain for which no other cause can be found.

2. The group of married women who have a congenital retroversion which gives rise to symptoms, on or after marriage, of which the commonest is dyspareunia; or they may seek advice for sterility; or, if they become pregnant, miscarriage may result. These patients require investigation and treatment.

3. The group of those who are found to have retroversion acquired after miscarriage or labour. This is a large and important group, as is shown by the record of two hundred consecutive confinements. Post-natal examination one month after delivery showed that of the primiparae 13 per cent. had retroversion; of the multiparae 3.5 per cent. had retroversion. These patients had received the advantage of skilled nursing and postural preventive treatment, so that the percentages are probably higher among the greater number of women attended in their own homes. These require treatment in order to prevent subinvolution after labour; the position of the uterus must be corrected in order to prevent the development of symptoms of pelvic discomfort, backache, congestive dysmenorrhoea, leucorrhoea, and dyspareunia. Further, if a retroverted uterus is left uncorrected after labour it will be a factor leading to future prolapse.

The pelvic discomfort is generally of a dull aching nature, aggravated by activity and fatigue. It may have a bearing-down character or may give rise to a sensation of fullness or pressure on the rectum. The backache is generally dull and constant, increased by fatigue and relieved by rest. It is generally felt posteriorly over the sacrum, but may radiate towards the iliac fossae or the thighs.

*Read in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Bournemouth, 1934.

Treatment of Congenital Cases

In the case of single women many require no treatment and should be left alone. In young married women complaining of dyspareunia or sterility or miscarriage the condition may be treated by manipulation and a pessary, or by operation. It is advisable to give a good trial to medical treatment before resorting to a surgical operation. When treatment is indicated for the above symptoms it is often found that correction of the displacement cannot be carried out as the manipulations cause pain, and it is difficult or impossible to correct the misplacement. In such cases it is advisable to carry out an examination under an anaesthetic.

The patient is anaesthetized, a thorough pelvic examination is made, and the body of the uterus is pushed forward either by the fingers alone or with the aid of a vulsellum forceps on the cervix. In difficult cases a uterine sound may be required to assist the reposition of the uterus. Having put the uterus into a satisfactory position, a Hodge pessary is inserted. This is left in for two or three months, and it is then removed and the position of the uterus after removal ascertained. If the uterus remains in good position after this treatment nothing further need be done. If, however, the uterus reverts to its old position after removal of the pessary, the question will arise whether to replace the pessary or to perform an operation. In order to arrive at a decision all the factors in the case must be carefully considered. If the position of the uterus cannot be corrected under an anaesthetic the indications for operative treatment appear greater, but generally speaking the indications for operation in single women do not often arise. In married women, on the other hand, symptoms are often sufficiently important to require treatment by pessary or operation.

Treatment of Acquired Retroversion

Seeing that retroversion is most often the result of pregnancy and labour, it is very important to adopt all precautionary measures which may prevent the occurrence of this displacement. The most important of these precautionary measures consist in promoting the free drainage and anteversion of the uterus during the puerperium. The puerperal woman should assume a prone position for at least two hours in the day. The bladder should be emptied at regular intervals, and the abdominal binder should not be sufficiently tight to press the fundus of the uterus back. Adequate rest in bed is essential, but it is difficult, for economic reasons, to arrange for hospital patients to stay in bed for more than twelve days. At the end of a month a post-natal examination should be made, and the position of the uterus determined. If the uterus is retroverted the position must be corrected by manipulation, and a Hodge pessary inserted for two months. At the same time the patient must be instructed to do all she can to promote involution of the uterus and pelvic floor by suitable exercises.

General lines of treatment fall under three headings: exercises, pessaries, and operation.

Exercises are most useful in helping to restore tone to the uterine supports after labour during the puerperium. They are helpful at a later date, but are of more value in restoring loss of tone than in repairing injury to the tissues. Further, their scope is limited, because it is difficult to give instruction in exercises designed to strengthen the levator ani muscle and the uterine supports, and it is even more difficult to get women to carry out these exercises except under expert instruction.

Treatment with Pessaries.—The vulcanite Hodge pessary is the instrument most suitable for temporary treatment of retroversion, and is far superior to the rubber ring for this purpose. Indications for its use are: (a) In mobile

puerperal retroversion after correction of the position of the uterus. The pessary should be left in two months, during which time the pelvic floor and uterine supports regain their normal tone. On removing the pessary the uterus should remain in a position of anteversion. (b) In non-puerperal mobile retroversion—that is to say, when the retroversion is discovered at some interval after the last confinement. Here the pessary treatment is not likely to effect a permanent cure, but will relieve symptoms and arrest the progress of the displacement. When used in these circumstances the pessary will act as a valuable diagnostic agent, for if symptoms are cured by its introduction it shows that they were due to the backward displacement of the uterus. This will be of value in deciding whether operative treatment should be undertaken. (c) Pessaries are useful after correction of a backward displacement in early pregnancy; the instrument will prevent the recurrence of the retroversion. The main indications for pessary treatment are as a therapeutic test and as a temporary measure in puerperal retroversion. When, however, pessary treatment cannot effect a permanent cure, and relapse occurs after removal, the time has come to consider the advantages of operative treatment.

Operative Treatment of Retroversion

The indications for operative treatment for backward displacement of the uterus are in some cases quite clear when symptoms are severe or cause the patient considerable discomfort, or cannot be alleviated by pessaries or other means. This may occur when the uterus is fixed and the ovaries are prolapsed and tender; when the retroversion is associated with pelvic inflammation; when there is dyspareunia; when there is sterility; and when there is abortion. A decision, on the other hand, may be difficult when the symptoms are not severe, and when the retroversion is uncomplicated.

The question of operation is influenced by the age of the patient less than are many operations, for the reason that after operation pregnancy and labour may supervene without any risk of complication or recurrence. Before deciding to operate it is most important to take a very thorough history, make a very complete examination, and to have no doubt that the symptoms referred to are not caused by anything apart from the displacement.

In order to ascertain the opinion of others as to the indications for operative treatment in uncomplicated retroversion a form of inquiry was sent to the senior gynaecologists at the London teaching schools. The result of this inquiry shows that operative treatment is not common. When it is done the commonest indications are sterility and dyspareunia. The present position seems to be against operative treatment in uncomplicated cases. This attitude should, I think, be modified, since there are many patients who suffer severe symptoms from an uncomplicated retroversion who could be cured by operative treatment.

The indications for operation are, in my opinion, as follows:

- (a) When the retroversion is fixed or is complicated by adhesions or by chronic pelvic inflammation.
- (b) When the retroversion is giving rise to symptoms, which are increasing, of backache, pelvic pain, menorrhagia, dysmenorrhoea, or pain and difficulty with micturition or defaecation.
- (c) When the retroversion, though mobile and simple, causes symptoms which disappear after correction of the displacement and insertion of a pessary—for example, dyspareunia.
- (d) When retroversion is causing sterility.
- (e) When retroversion is causing miscarriage.

In uncomplicated cases it is important to use a pessary as a therapeutic test before deciding in favour of operation; if the pessary relieves the symptoms, permanent cure by operation may be looked for with confidence.

Nature of the Operation

The operation of choice is that generally described as the modified Gilliam operation, after the name of the surgeon who first described this operation in the year 1900. The principal points in the operation are that a loop of the round ligament on each side is brought out under the peritoneum and attached to the anterior rectus sheath on each side. Details of the operation are as follows.

The abdomen is opened by a paramedian incision. A stitch of No. 3 chromicized catgut is tied about the round ligament on each side an inch from the cornu of the uterus. The anterior rectus sheath is then cleared, and a small puncture is made towards the outer part at the level of the fundus of the uterus. A special curved forceps is then passed outwards behind the peritoneum till the region of the internal abdominal ring is reached. The forceps then turns inwards in the base of the broad ligament till its point reaches the ligature on the round ligament. The peritoneum is then punctured, the round ligament suture grasped with the forceps and withdrawn along the track made by the forceps through the rectus sheath. The loop of round ligament is then made fast to the rectus sheath and the abdomen closed. The suture material used is No. 3 chromicized catgut, as this has been found satisfactory and no recurrence has occurred.

This operation has stood the test of time and has given complete satisfaction. It has therefore seemed unnecessary to change the technique of the operation or the suture material. In order to confirm these points, letters were written to patients operated upon from two to fourteen years ago, inquiring as to the result of the operation. The replies were illuminating and highly satisfactory.

Modifications of Operation

In order to test my own results I sought the opinion of the senior gynaecologists of the London teaching schools as to the nature of operation employed. All appear to employ a modified Gilliam operation, and find it eminently satisfactory. Many seem to prefer the use of silk, and some think it essential. Many, however, give up puncturing the rectus sheath, and draw the loop of round ligament up between the outer surface of the rectus muscle and the under surface of the rectus sheath. One operator pleats up the round ligament before drawing it through to the under surface of the rectus sheath, to which it is firmly attached by silk, thus approaching the technique of a fixation operation. Another operator pleats up the round ligaments and attaches them to the cornu of the uterus; while a third combines the ventral suspension of the uterus with shortening of the utero-sacral ligaments. Except for these three modifications, all do the modified Gilliam operation, and are satisfied with the results. The majority use silk sutures, but I have found chromicized catgut satisfactory, and think that silk introduces a possible element of sepsis.

Conclusions

Retroversion of the uterus is responsible for a considerable amount of ill-health in women. It may be prevented or cured during the puerperium by suitable exercises and treatment.

Congenital retroversion in single women often causes no symptoms and requires no treatment.

Congenital retroversion in married women does cause symptoms.

Retroversion acquired after labour or miscarriage is common, and the importance of preventive treatment is stressed.

Acquired retroversion often gives rise to symptoms, and requires correction by pessary or operation.

HAEMOPTYSIS: A NOTE ON PATHOLOGY AND TREATMENT

BY

H. V. MORLOCK, M.C., M.D., M.R.C.P.

AND

A. J. SCOTT PINCHIN, M.D., F.R.C.P.

PHYSICIANS TO CITY OF LONDON HOSPITAL FOR DISEASES OF
HEART AND LUNGS

Haemorrhage from organs such as the lungs and intestines, which are not accessible to the ordinary surgical methods of haemostasis, present a problem which is peculiar to itself; for not only does the practitioner feel more or less helpless, as he is unable to reach the bleeding point, but the psychological effect on the patient of bringing up large quantities of blood—whether from lungs or stomach—together with the knowledge that the lesion is not accessible, leads to a distress of mind which reacts unfavourably on the natural processes which should physiologically help to stay the haemorrhage.

The usual treatment recommended for haemoptysis is along the general lines suggested for the arrest of bleeding when not accessible to direct methods of haemostasis; these general methods have two objects in view, which are as follows. In the first place, to secure a local effect by the administration of drugs or other preparations which have the reputation for promoting clotting at the source of the haemorrhage by increasing the coagulability of the blood; secondly, to endeavour to rest the organ from which the bleeding is taking place, and by sedatives to quiet the body, ease the mind, and so cause a reduction in the rate of flow of the blood.

Preparations used in the first group, such as calcium, haemostatic sera, horse sera, etc., whilst possibly of some use are somewhat unreliable in their action, and, in consequence, though used as a routine, they are regarded as rather accessory, and there is a natural tendency to place most reliance on those methods which will promote mental quiet and physical rest to the organ from which the haemorrhage is proceeding, and thus give the bleeding vessel the opportunity of forming a clot sufficient to stay the haemorrhage.

Pathology and Mechanics of Haemoptysis

Should these methods be successful in stopping the haemorrhage the arrest is only slowly produced, with the result that some bleeding will continue to take place for varying periods, according to the size of the vessel eroded, while in addition any movement or disturbance of the patient may cause the haemorrhage to recommence, and as a result a considerable amount of blood will be found in the lumen of the organ concerned.

If the bleeding is intestinal the blood in the lumen will be drained into the intestinal tract, but in a haemoptysis the blood remains in the bronchus and can only be evacuated therefrom by the patient coughing; if, however, the patient has been forbidden to cough, and has been heavily morphinized, the cough reflex will be lost, and the blood will remain in the bronchus. It is well recognized that even during natural sleep secretions from the upper respiratory tract may be aspirated into the lower bronchi; further, it is admitted that, when unconsciousness is increased by morphine or basal anaesthetics, aspirated secretions may cause a pulmonary collapse. In the morphinized patient, with blood or blood clot in the bronchial tree, the chances of mechanical pathological changes taking place are very considerable.

If the quantity of blood in the bronchus is small, aspiration into the smaller bronchi and bronchioles will take place; further, if the patient gives a half-stifled ineffective cough, the blood will be evacuated from the

bleeding bronchus as far as the bifurcation of the trachea, or into the trachea itself, ready to be sucked down by the next inspiration, not only into the diseased lung, but into the healthy one as well. If the cause of the haemoptysis is a septic or a tuberculous lesion, organisms will be aspirated with the blood and will often give rise to a spread of the infection. This spread of the disease is indubitably seen to occur in septic conditions, and is not uncommon in tuberculosis. The reason that it does not occur more often is probably the dilution obtaining in large haemorrhages. If the haemorrhage is a copious one the coagulated blood often forms a clot within the bronchus, which clot is sometimes large enough to occlude a main bronchus, thus producing a sudden complete collapse of a lobe or even the whole lung; moreover, if by an ineffective cough the clot be extruded into the trachea, aspiration may take place into the main bronchus of the sound lung and cause a complete collapse of it.

Illustrative Cases

These mechanical pathological lesions are not merely theoretical possibilities, but are practical facts which we have ourselves observed and of which the following cases are examples.

Case I.—Male, aged 45, suffered from haemoptysis which was treated on general lines. A skiagram taken a few days later showed in the right upper lobe a lesion bronchopneumonic in distribution which was thought to be a tuberculous condition. Two weeks later a skiagram showed collapse of right upper lobe; on bronchoscopic examination we could see new growth occluding the upper lobe bronchus. There can be little doubt that the bronchopneumonic area seen on the first skiagram was produced by lobular collapse secondary to aspirated blood.

Case II.—Male, aged 22. Haemoptysis treated on general lines. When admitted to hospital definite signs at left upper lobe, with signs suggestive of a small area of bronchopneumonia in the right axilla. Sputum, T.B. +. To control the haemoptysis left artificial pneumothorax induced. Haemoptysis ceased and patient improved. Skiagram at this stage confirmed diagnosis of left-sided pulmonary tuberculosis, and showed a small area of bronchopneumonia of lobular distribution in right axilla. Artificial pneumothorax kept up. Sputum became negative. Area in right axilla cleared. We believe that the area in the right axilla was an aspiration spread due to the haemoptysis. It might be argued that it was the spread that led to the haemoptysis, but against this is the fact that it was controlled by the left-sided artificial pneumothorax. As no films were available previous to the haemoptysis the point cannot be definitely settled.

Case III.—Female, aged 40. Patient had a benign growth of left main bronchus. During an attempt to remove the growth by diathermy severe haemoptysis occurred, which was uncontrollable by diathermy and adrenaline. Within twenty-four hours the previously afebrile patient developed a high temperature, with signs of pulmonary collapse of lobular distribution. This was treated by expectorant mixtures and CO₂ inhalations, and the signs in the chest cleared. This sequence was repeated when a second attempt was made to apply diathermy to the growth.

Case IV.—Female, aged 23. Patient had the same type of growth, and diathermy treatment was followed by same sequence of events as in the previous case.

Case V.—Male, aged 16. Large haemoptysis, treated by absolute rest and morphine. On his admission to hospital the physical signs in the chest were those of complete collapse of the left lung. Skiagrams confirmed the diagnosis. The haemoptysis having nearly ceased, it was decided to risk further haemorrhage and to deal with the collapse by CO₂ inhalations and expectorant mixtures, with the result that the clot was expectorated, and in the course of a few days the left lung re-expanded to show a comparatively small tuberculous lesion in the mid-zone.

Case VI.—Female, aged 20. Patient was known to have a small unhealed lesion in right upper zone, and was admitted

to hospital following a large haemoptysis which had been treated on general lines. A few indefinite signs were found in the right lung, and signs of complete collapse of the left lung. This was confirmed by skiagram. After a few days following the coughing of clotted blood, the left lung expanded completely, and the skiagram showed no evidence of any disease in it.

Haemostasis by Congo Red

Experience as exemplified by these cases has led us to the conclusion that the measures adopted under the second group—that is, the use of opiates—are not without danger, and this applies to any drug which definitely abolishes the cough reflex. It would seem not unnecessary that this point be stressed, for one seldom sees a case of haemoptysis in which a large dose of morphine has not been previously given. We agree that it is necessary to reassure the patient, to lessen his anxiety, and to put his mind and body as much at rest as possible, but we are convinced that it is bad treatment to order the patient not to cough, and deliberately to attempt to abolish the cough reflex.

It is well to point out that in early tuberculosis, in acute septic pneumonitis or lung abscess, or in haemorrhagic bronchiectasis, it is seldom that a haemoptysis is severe enough to endanger life, and therefore it is certainly not justifiable to employ a method which may by its application cause a spread of disease. On the other hand, in the advanced tuberculous case with large rigid-walled cavities, in malignant growth, and in leaking aneurysm the prognosis is in any case so poor that the objection to morphine does not hold.

If the use of sedatives is inadvisable it is certain that endeavour must be made to find some reliable haemostatic; those mentioned above have been in use a sufficiently long period of time to prove their deficiencies, though they certainly have their place in treatment. For some two years, in those cases in which haemostatics of this class had failed to effect a result, we have used an intravenous solution of Congo red. This haemostatic appears to have been little used in this country. It was recommended by Becker *et alia* in 1930 for use in haemorrhage.

The precise pharmacological action is not known, but Sachette and Osseladore¹ found that after the intravenous injection of neutral substances into rabbits, changes in the clotting time of the blood took place. In the beginning this change was accompanied by a numerical variation in the thrombocytes, and they formed the conclusion that the reticulo-endothelial system, especially the bone marrow, influenced the production of the thrombocytes.

Becker² *et alia*, from examination of the blood of their cases before and after the injection of Congo red, came to the following conclusions. That the Congo red produced: (1) an increase in the monocytes, (2) an increase in blood platelets, (3) an increase in blood fibrin content, and (4) a reduction in clotting time.

Technique.—The technique of administration is that of a simple intravenous injection, though, the colour of the solution being a deep red, some difficulty may be experienced in knowing when one has entered the vein. We have found from experience that dosage is of considerable importance. For an adult the dose usually given is 10 c.cm. of a 1 per cent. solution. This dose is often followed by a definite rigor of short duration which never gives cause for alarm. In an attempt to avoid the rigor we have tried smaller doses, and have found that although they may succeed in checking the haemorrhage temporarily they are not as successful in obtaining complete stasis as is the full 10 c.cm. dose. We have not so far had need to give a larger initial dose

than 10 c.cm., and from our experience in one case in which by an error double the dose was given we doubt if an increase is advisable, for in that case the patient developed a severe rigor with an alarming collapse; nevertheless, the haemorrhage which had menaced his life and had failed to be controlled by other haemostatics ceased instantly. We have found that occasionally the 10 c.cm. will check the haemorrhage for some time, and then slight recurrence occurs. In such cases the dose may be repeated, a further 10 c.cm. being given in four to six hours. In a large number of cases treated with this drug we have only had two in which the haemoptysis was not sufficiently controlled and other methods were necessary.

Other Methods

In cases of gastric and duodenal haemorrhage results have also been satisfactory, though perhaps not quite so certain as in haemoptysis. Other methods of obtaining stasis which have been suggested, such as the introduction of adrenaline into the bronchial tree, have not impressed us with their efficacy. Adrenaline may be introduced by the nasal catheter, crico-thyroid route, or by the bronchoscope. We have used the first two methods, but in any case the solution is so diluted with blood that effect can scarcely be expected; moreover, the bleeding point is usually so distant in the bronchial tree that it is unlikely that any direct result could be produced. Quite different are the severe and somewhat alarming haemorrhages which occasionally take place in the removal of polyps or a section of malignant growth via the bronchoscope; in this case adrenaline can be applied direct in large quantity over the bleeding area.

In the event of failure of other methods, the induction of an artificial pneumothorax is often successful in staying the haemorrhage. The cause of the haemoptysis must, however, first be considered. If the lesion is an early tuberculous one it will probably be successful, but in these cases the bleeding is usually not so severe as to cause alarm; if the lesion is in an advanced bilateral case artificial pneumothorax may be done as a temporary measure, even if it may be deemed inadvisable to keep it up permanently. In this type of case difficulty may arise in deciding as to the side from which the haemorrhage is coming. If an x-ray is available then the side showing a cavity is the most likely to be the offender, if not, one has little guide, as the ordinary methods of physical examination are not available. Often, however, the patient knows which is the worst side, and in many instances is able to indicate the side from which the bleeding is coming from subjective sensations. But as a contralateral artificial pneumothorax may be successful in stopping the haemorrhage, the position is not quite so difficult as it might appear. If the lesion is a lung abscess or a bronchiectasis, one must weigh up very carefully the urgency of the haemoptysis with the risk, especially in the former case, of producing a pyo-pneumothorax. Occasionally repeated haemoptyses call for some preventive measure. Such are frequently cases of dry bronchiectasis and chronic fibrosis, and an artificial pneumothorax or phrenic avulsion may be a useful procedure.

Conclusions

In a pulmonary haemorrhage the bronchi must be kept free. This can only be attained by leaving the patients their cough reflex. Some method of haemostasis is desirable, and in the failure of the ordinary methods Congo red has proved in our experience to have a very definite use.

OBSERVATIONS ON THERAPEUTIC MALARIA

WITH SPECIAL REFERENCE TO A CASE
OF HAEMOGLOBINURIA

BY

C. B. BÄMFORD, M.D., M.R.C.P., D.P.M.

ASSISTANT MEDICAL OFFICER, RAINHILL MENTAL HOSPITAL

Malaria is still the most popular of all forms of treatment for general paralysis in spite of the numerous attempts which have been made to supersede it by other forms of pyrexial therapy. Its popularity with clinicians is derived not so much from the high measure of complete recoveries achieved as from its relative immunity to serious accidents. In thus combining a moderate degree of success with comparative safety, it has proved itself superior to, and generally more acceptable than, any of its rival methods of treatment.

The truth of this claim has been amply borne out by our experience of some 300 cases of therapeutic malaria during the last ten years at Rainhill Mental Hospital. With a judicious selection of cases the number of untoward complications has been almost negligible, and the great majority of patients have succeeded in completing a course of ten rigors, with associated rise of temperature, at no greater cost to the patient than a mild prostration and some degree of anaemia. With adequate after-treatment both of these temporary set-backs have been successfully combated. In about 10 per cent. of the cases a mild degree of jaundice has been observed, associated with the anaemia appearing towards the end of the malarial course, but in all instances clearing up completely after the administration of quinine.

Both the benign tertian and quartan forms of malaria have been employed at different times, but of the two the former has proved the more satisfactory. In our experience the quartan is less reliable, and not so readily controlled with quinine. Despite this, relapses are of very rare occurrence. As will be noted from the accompanying temperature chart the rigors sometimes occur at much more frequent intervals than is characteristic of this strain of malaria. This phenomenon is by no means an uncommon experience with therapeutic malaria, particularly after many generations of the parasite have passed through the human host, and in our opinion is attributable to the fact that propagation is carried on solely by the asexual cycle for so many generations. Blood films examined from such sources show that the parasites mature at different periods, and in the same sample of blood parasites at all stages of development are to be seen. This offers some explanation of the irregular pyrexia, but, in addition, there is some evidence for thinking that there may be a personal factor also concerned.

Case Record

A case which provides an outstanding exception to this general experience has recently been encountered at Rainhill, and because of its unusual features it is deemed worthy of a detailed consideration.

G. H., a male, 46 years of age, was recently admitted to the hospital in a restless, excited, and grandiose state. He had typical delusions of grandeur, and clinically presented a classical case of general paralysis. Though he had few neurological signs, the clinical diagnosis was amply confirmed by serological tests. Thus the Sigma reaction in blood and cerebro-spinal fluid was strongly positive, there was increased protein in the cerebro-spinal fluid, and the large gold-sol curve read 5555554100. The mental symptoms had only been in evidence for just over a fortnight prior to his admission, and as he was in good physical condition there was no hesitation in prescribing for him a course of malaria. Before

inoculation with 5 c.cm. of malarial blood (2/2/34) his acute mental symptoms had considerably subsided, and he had regained to some extent his insight, a circumstance which rendered his subsequent management and nursing very easy. Eleven days after his inoculation (13/2/34) he had his first rigor, and this was repeated at roughly twenty-four-hour intervals for ten days, with an associated temperature averaging 104°F . On two occasions during the course blood films showed the presence of malarial parasites of the quartan variety with a relative increase in the mononuclear leucocytes. After the tenth rigor (23/2/34) quinine was given orally in mixture form (quinine sulphate, 10 grains t.d.s.). Twenty-four hours later (24/2/34), after he had received five doses of quinine, he had a very severe rigor, with a temperature of 105° , the highest recorded. This unexpected and unusual event gave rise to considerable misgivings, but quinine was continued. Two days later (26/2/34) his temperature rose again to 99.6° without any rigor, and the same day a definite icteric tinge appeared on his skin, whilst a little later his urine was observed to be unusually dark in colour. The following day (27/2/34) the jaundice had deepened, and the urine was diminished in quantity and of a deep red colour.

At this stage a sample of blood taken for examination revealed a marked degree of haemolysis, the serum being of a reddish hue instead of the usual straw colour. An examination of a blood film showed severe anaemic changes with anisocytosis, polychromatophilia, and punctate granular cells. There were numerous normoblasts and a few megaloblasts. Among the white blood cells there were myeloblasts and myelocytes in all stages. The urine contained a large amount of haemoglobin, and spectroscopic examination of both urine and blood serum showed the bands characteristic of oxyhaemoglobin. Another abnormal constituent of the urine, which was alkaline and of high specific gravity, was albumin, present in considerable amount, but there was no deposit of red blood cells or casts. The test for occult blood was strongly positive.

Progress.—This association of malaria, quinine, and haemoglobinuria strongly suggested a diagnosis of blackwater fever, and prompt and vigorous measures were taken to meet this very serious situation. Quinine was stopped (28/2/34), copious drinks were given, and large massive doses of alkalis administered, whilst a careful watch was set upon the quantity and colour of the urine passed. Remarkable to relate, despite this severe haemolysis the patient, who was very clear mentally, had scarcely any subjective symptoms. He made no complaints at all beyond his feeling of weakness, but stated at a later period that for a short time he had seemed a little deaf.

His condition responded exceedingly well to treatment. He passed large quantities of urine, which gradually cleared and became free from haemoglobin and albumin in four days (3/3/34). His blood picture improved *pari passu*, a distinct improvement in the blood films being observed very quickly (2/3/34). The progress of the blood condition may be gauged from the following reports.

2/3/34—Blood film shows an occasional normoblast; anisocytosis still very marked. Haemoglobin 80 per cent.

3/3/34—Blood count: red blood cells, 2,800,000 per c.mm.; white blood cells, 7,500 per c.mm.; colour index, 1.4. Leucocytes consist chiefly of myelocytes in various stages of development.

5/3/34—Blood film shows an occasional normoblast, also many myelocytes. Red blood cells show less marked anisocytosis but severe achromia.

7/3/34—Halometer reading of red blood cells, 7.32 μ . Blood count: red blood cells, 2,800,000 per c.mm.; haemoglobin, 60 per

cent.; colour index, 1.07. Well-marked anisocytosis still, but no normoblasts seen. Considerable improvement on previous films. 16/3/34.—Blood count: red blood cells, 4,100,000 per c.mm.; haemoglobin, 70 per cent.; colour index, 0.85. Numerous reticulocytes seen in film. Halometer reading approximately 7.32 μ . 5/4/34.—Blood count: red blood cells, 4,600,000 per c.mm.; haemoglobin, 85 per cent.; colour index, 0.9. Only an occasional reticulocyte seen. Halometer reading 7.48 μ .

As will be seen from the report of the last blood examination, the man's blood picture approximated closely to normal. Clinically, his general bodily condition showed corresponding improvement, but at the time of writing (April, 1934) he still has a mild degree of tachycardia—a residuum, no doubt, of the profound degree of anaemia. His mental condition is very satisfactory, and he will shortly be discharged from hospital as fit to resume outside life and pursue his former occupation.

Discussion

The quartan strain of malaria employed in this case had already passed through two female patients, who throughout the course of treatment of the usual length had not manifested any unusual or alarming symptoms.

Further, another male patient, inoculated simultaneously and with the same blood, ran the course in the usual way. The possibility of a previous malarial infection either of the malignant or benign form has been definitely excluded by investigation of the man's previous history.

If it serves no other purpose, this phenomenal case illustrates the obscurity

with which the aetiology of blackwater fever is still surrounded. There would have been no hesitation in labelling this case as one of true blackwater fever if the malaria had been of the malignant variety, for in this case most of the characteristic features of this disease made their appearance in the usual sequence. Thus there was the malarial course terminated by quinine, and this, in turn, followed by the intravascular haemolysis, resulting in haemoglobinuria, jaundice, and anaemia. As in most cases, it is very puzzling to assess the importance of the part played by quinine in the production of this condition, but it is very significant that the symptoms appeared immediately after the administration of the drug, a feature of the aetiology which is much emphasized in textbook descriptions. Other causative factors of haemoglobinuria can be dismissed—namely, drugs (for example, potassium chlorate), over-exertion, excessive cold, as in the paroxysmal haemoglobinuria variety, in which in the last-mentioned case there would in all probability have been previous attacks.

Whatever may be the nature and source of the lysis producing such severe haemolysis, it would seem from the experience of this singular case that a condition identical with, or strongly resembling, blackwater fever can arise after benign malaria treated with quinine as well as after the malignant form. The complete absence of any reference to this possibility in all standard textbooks of medicine testifies to the extreme rarity of the condition.

In conclusion, I gratefully acknowledge my indebtedness to Dr. F. Murgatroyd of the Liverpool School of Tropical Medicine for his invaluable advice and interest, and also to Dr. E. F. Reeve for permission to publish this case.

Temperature Chart of Malaria, showing Rigor occurring after Administration of Quinine. Rigors occurring at Daily Intervals (with the exception of the fourth day).

PREVENTION OF INTRACRANIAL INJURIES OF THE NEWBORN

BY

ROLAND H. NATTRASS, M.B., B.S. MELB.

RESIDENT OBSTETRIC SURGEON, ST. MARY'S HOSPITAL, MANCHESTER

During a period of six months I performed necropsies on 107 consecutive natal and neo-natal deaths at the above hospital. Excluding fourteen of these cases which had perforations performed for varying causes, forty-three of the remaining ninety-three cases were found to have intracranial lesions—that is, in 46 per cent. of all these consecutive deaths there were intracranial injuries. The lesions present were lacerations of the tentorium cerebelli in most cases, and usually associated with haemorrhages or oedema of adjacent parts; occasionally the falx cerebri was also lacerated.

There is not the slightest doubt that a large proportion of infants who survive have intracranial injuries; the greater number of these will have no more than small tears of the tentorium and oedema of adjacent parts, but others may survive where relatively large haemorrhages have occurred, and I have seen a great amount of blood removed in two cases where I performed repeated bi-daily cisternal punctures for four days and the infants at the time of discharge appeared to be normal. Although the presence of these injuries in the newborn has been recognized as far back as 1829, their tremendous importance as regards infantile mortality has not been stressed until the last few years, and even now some modern obstetrical textbooks do not seem to appreciate their great importance.

The purpose of this short article is not to determine the treatment of these injuries, but to find methods by which these injuries may be prevented.

Mechanical Causes of Injury

Numerous theories have been brought forward as to the method of production of these injuries, but it is more commonly agreed now that a mechanical factor is the direct cause of the injury, due to alteration in shape and compression of the foetal head. This is accompanied by stretching of the supportive apparatus, particularly the tentorium cerebelli. This mechanical effect of alteration in shape and compression is most marked in cases where there is excessive moulding, or where the change in shape of the foetal skull is accomplished too quickly by an operative delivery.

If there is excessive moulding, the effect of lateral compression is to raise the vault of the cranium, so increasing the strain on the falx and tentorium. The prevention of this excessive moulding can be carried out only by efficient ante-natal care in watching for disproportion between size of foetal head compared to maternal pelvis, and performing induction of labour before term or, if necessary, Caesarean section at term. This is one big factor in preventing intracranial injuries.

Breech Deliveries

Another extremely common cause of these injuries is in extraction of the after-coming head in breech deliveries. Bourne in 1922 found that breech delivery is ten times more likely to give rise to cerebral injuries as compared with vertex deliveries. In my series every breech mortality (six) had, at necropsy, intracranial injuries. To prevent these injuries in breech deliveries it is most important that the still unmodelled head should not be drawn violently through the pelvis and so cause sudden compression and, in this way, rapid stretching of the cranial supports. Also the routine procedure of performing a

lateral episiotomy in every case of breech delivery is a great help in preventing the sudden application of, and then sudden release of, compression on the foetal head due to an unstretched perineum.

Again, in breech deliveries care should be exercised in applying suprapubic pressure on the after-coming head, especially as this pressure is applied to the foetal skull in a vertical direction, and so is more liable to produce stretching of the cranial supports. Some obstetricians favour the routine application of forceps on the after-coming head as opposed to applying any suprapubic pressure on the head, thus avoiding pressure in a more dangerous direction.

Misuse of Forceps

As regards the use of forceps, these alone should not increase the risk of intracranial injuries unless associated with other factors as marked disproportion, or the wrong application of forceps, especially a fronto-occipital application. If forceps are being used, it is advisable to use axis traction, even in low forceps deliveries, to avoid premature extension of the head, which causes pressure of the occiput against the pubic arch with increased possibilities of intracranial injuries.

An unexpected cause of injury may result from the use of forceps of wrong size. One well-known firm sent to me a new pair of axis traction forceps with the widest diameter between the blades of exactly $2\frac{1}{2}$ inches instead of the usual $3\frac{1}{2}$ inches. Pulling on the forceps with this ridiculously small diameter would certainly cause intracranial injury, so it is a wise plan to check the separation of the blades from time to time, and also the shape of them, as after much use it is surprising how they can alter their correct shape.

Other Causes of Intracranial Injury

Another common cause of intracranial injury is the use of pituitrin in a case with incompletely dilated cervix or with a rigid perineum. The use of pituitrin in these cases may quickly force the foetal head through this obstruction, with resultant cranial injury. Again, precipitate labours are a frequent cause of similar damage, as the sudden compression followed by sudden release results in injury.

In premature labours one must be exceedingly careful in the delivery of these cases, as premature infants are notoriously prone to develop intracranial injuries, no doubt due to abnormal fragility of the vessel walls, and of the dura, etc., due to incomplete development of fibres of dura.

In delivering a normal case in the interval between uterine contractions, with the head on the perineum, one must be careful not to push too forcibly the foetal forehead against the pubic arch by a finger on the perineum or in the rectum, as such pressure may be enough, especially in a premature infant, to injure the supportive apparatus.

An indirect method in the prevention of these injuries is applicable in those cases with an irregularity or change in rate of foetal heart sounds. Usually these changes are due to compression on the foetal skull, and the treatment is not to apply forceps and deliver as rapidly as possible, and so increase the likelihood of intracranial injury, but to use chloroform, which will lessen the uterine contractions.

Efforts at Resuscitation

The last important point in the prevention of these injuries, or in this case I should say in preventing the increase of intracranial damage, is the manipulations during resuscitation. It is most important to remember

that practically all asphyxiated newborn infants which do not respond to treatment within the first minute or two are suffering from intracranial injuries, and that the older and violent methods of resuscitation, if used, will further increase these injuries by causing increased haemorrhage. If an asphyxiated infant is going to respond to any form of resuscitation, I am sure no more treatment is needed than to remove any mucus from the throat, and to encourage attempts at respiration by gentle traction on the tongue with tongue forceps at the rate of about twenty pulls per minute, together with the injection of a cardio-respiratory stimulant such as coramine or icorol.

Should the infant attempt to breathe, carbon dioxide is here of some use. The older methods of throwing the child from one hand to the other or of violently flexing its body should never be allowed to be used on an asphyxiated newborn infant, as all such infants should be considered as having potential brain injuries, and small haemorrhages may soon prove fatal if unnecessarily aggravated by vigorous manipulations during resuscitation.

RECURRENT VOMITING ATTACKS IN CHILDHOOD

WITH SPECIAL REFERENCE TO ALLERGIC FACTORS*

BY

K. H. TALLERMAN, M.D., M.R.C.P.

ASSISTANT PHYSICIAN TO THE CHILDREN'S DEPARTMENT, LONDON HOSPITAL; PHYSICIAN TO PADDINGTON GREEN CHILDREN'S HOSPITAL

Recurrent attacks of vomiting, or so-called "bilious attacks," occur with sufficient frequency in childhood to be of real importance in clinical practice. Though not usually causing prolonged illness, they are often most inconvenient to the children concerned on account of their repeated interference with school life, while they may at times be severe enough to necessitate admission to hospital.

Wyllie and Schlesinger¹ have recently discussed a group of cases of this type under the heading of "The Periodic Group of Disorders in Childhood." Such a title has certain advantages, the chief being the emphasis it lays upon the tendency of these attacks to recur. "Cyclic vomiting" is a term often used for the attacks, but this rather implies a regularly recurring cycle, and any absolutely regular periodicity of the attacks is actually very rare, if indeed it ever does occur. Again, these children are often said to be suffering from attacks of acidosis. This is mentioned in order to draw attention to the fact that there is usually no justification whatever for such a diagnosis, although acidosis may accompany severe attacks of vomiting. It is of course well known that at the time of attacks these children do suffer from varying grades of ketosis. The term "ketosis" is, however, by no means synonymous with acidosis, and in fact true acidosis is not usually met with in childhood except as a relatively rare accompaniment of such diseases as diabetes, nephritis, and acute gastro-enteritis.

The aetiology of the recurrent attacks of vomiting under discussion is by no means clear. They are probably a manifestation of some metabolic disturbance, and Josephs² has shown that they may be associated with a hypoglycaemia. This being so, the accompanying ketosis is therefore explicable on the basis of an insufficient supply of carbohydrates being available for the proper metabolizing of fats. In these patients the clinical improvement effected by restricting fats and giving glucose is evidence favouring this explanation. It should, however, be mentioned that not all cases show a hypoglycaemia, and that

the theory of hypoglycaemia as an important aetiological factor has not been definitely established. Whichever is primary, the ketosis or the vomiting, the fact remains that between attacks these children are generally healthy, with, so far as one can judge, no evidence of ketosis or of any other metabolic disturbance, and one is still ignorant as to the exact factor which initiates an attack. It has been shown that some at least of the children can tolerate a definite ketosis produced artificially without an attack being precipitated.

It is recognized that gastro-intestinal symptoms may be a manifestation of allergy, and Rowe³ regards gastro-intestinal food allergy as occurring most frequently in infancy and childhood. It appears quite possible, therefore, that allergy may play a part in the production of these recurrent attacks of vomiting, and that sensitivity to some foodstuff may be a determining factor in their onset. With this aspect of the problem particularly in view, the following study was undertaken.

Investigation of Forty Cases

So far as possible, all children were selected for study who came to my out-patient sessions in the Children's Department of the London Hospital between January, 1932, and August, 1933, suffering from recurrent vomiting attacks. Personal and family histories were investigated, all significant data in regard to clinical findings were recorded, various investigations were carried out, treatment was prescribed, and progress was followed in each case. An attempt was then made to correlate the findings in the entire series, and to draw conclusions therefrom. As in every case reliance had to be placed on the history obtained from the mother and upon her account of subsequent progress, it was obvious that accuracy in certain of the data was open to question. This, however, is invariably the case in any clinical study of this nature involving observation of out-patients.

The series here presented consists of forty cases; as is inevitable, certain other patients who were originally included defaulted before adequate observations could be carried out, and had therefore to be omitted. Of this series all the children attended quite regularly except three, each of whom for some time failed to come up as requested. The maximum period of observation was twenty-seven months and the minimum five months. The average period of attendance during which observations were made was sixteen and a half months; only two children were observed for less than six months. Reports of progress were subsequently obtained in regard to four of the children after attendance had lapsed.

Character of Attacks

It soon became apparent that there was no absolute uniformity in the duration of individual attacks, and, generally speaking, no regular periodicity in their occurrence. Often a child who was, at the time of first attendance, said to have an attack every two or three weeks, was found thereafter to have such attacks only at very infrequent intervals. Even in the history given by the mothers any account of regularity of attacks was infrequent. It is really impossible to make any useful analysis of the frequency or duration of these attacks. In most cases the vomiting was accompanied by headache, which was sometimes the most outstanding feature of the attack. This will be discussed later.

The average age at the time the children were first examined was just under seven and a half years. In twelve cases the attacks were said to have commenced before the age of three years, in thirteen cases the onset apparently occurred between the ages of three and five years, and in fifteen cases between the ages of five and ten years.

* From the Children's Department, London Hospital.

Precipitating Cause

In twenty-three of the cases the mother stated that she had no idea what initiated the attacks; in the remaining seventeen cases various factors, such as fatty foods or excitement, for example, were suspected to be associated with the onset of an attack. From these histories, however, one is forced to take the view that any exact knowledge of what precipitates an attack must be uncommon. Excess of fats does, however, appear to be a factor in certain cases, and some of the children in the group observed have a dislike, possibly physiological, of fatty foods. Constipation may well be an associated factor, but discussion of this is apt to be misleading on account of the difficulty of obtaining a reliable history in this respect. It should be recognized that the criteria among hospital out-patients as to normal and abnormal actions of the bowels are extraordinarily variable and frequently fantastic.

Allergic History

The allergic history is a matter of some importance, in view of the fact that it had been considered that the attacks themselves might be of an allergic nature. Of the forty children, four gave a personal history, present or past, of some manifestation usually regarded as allergic—namely, asthma (one case) and urticaria (three cases). In eighteen cases—that is, 45 per cent.—a family history of allergy was obtained, this being very pronounced in five. As it seemed possible that such a proportion of family histories of allergic manifestations might well be obtained in any similar group of children, a control series was investigated. Forty children attending hospital as out-patients, who gave no history at all of bilious attacks or headaches, were taken without selection. None of these gave a personal history of any allergic manifestation. A family history of allergy was obtained in only ten—that is, 25 per cent.—of this control group, and in only three of these was such family history really pronounced. There is therefore a much higher incidence—almost double—of history of allergic manifestations in the families of the children suffering from vomiting attacks than in those of the control series of cases.

Skin Tests, Blood Counts, and Gastric Acidity Tests

Each child in the series was skin-tested with extracts of all the articles of food usually regarded as most commonly responsible for producing allergic phenomena. The extracts used for testing were put up by Messrs. Duncan, Flockhart and Co., and consisted of: wheat, oatmeal, rice, potato, egg white, whole cow's milk, cocoa, beef, pig group (pork, bacon, lard), crustacea (group extract), and fish group (cod, herring, haddock, whiting, plaice, mackerel). A control solution was also employed in carrying out the test. Before applying the test the arm was in every case gently washed over with spirit. The results were very disappointing. In only one case was a slight but definite positive reaction obtained, this being to egg; in this case the mother had stated, on first bringing the child to hospital, that no food appeared to upset her. In five other instances certain reactions were regarded as possibly positive, but clear-cut positive reactions were not obtained, except in the one case mentioned. Skin testing in these children proved, therefore, to be of no assistance. It is, however, recognized that a negative skin test does not necessarily mean that a child is not allergic to the substance tested, and Rowe³ states that skin reactions are infrequently obtained in cases of gastro-intestinal allergy.

Blood counts were carried out in all except one of the cases, because of the fact that eosinophilia is generally accepted as being an accompaniment of the allergic state. No child in the series showed a conclusive eosinophilia,

but in seven cases the eosinophil count could at some time be regarded as slightly above normal, amounting to between 5 and 9 per cent.

It has been shown that in certain allergic conditions there exists a hypochlorhydria and a tendency towards alkalosis (Bray,⁴ Beckman⁵). With this in view test meals were carried out on thirteen of the children under investigation, who were admitted to the ward for this purpose. These cases were selected as being the most likely to yield significant results in view of a definite associated family history of an allergic nature. The meal given was the ordinary Ewald meal, on an empty stomach. Possibly different results for secretion of acid might have been obtained if histamine had previously been injected, or if fractional test meals had been employed, as in Bray's⁴ series of cases. At the same time, since a control series was treated in exactly similar fashion, it seems justifiable to make a comparison between the results of a simple Ewald meal in the two groups.

In seven of the cases investigated free hydrochloric acid was found to be absent. In two it amounted to 0.04 per cent., in one to 0.05 per cent., in one to 0.07 per cent., in one to 0.08 per cent., and in one to 0.17 per cent. The percentages given are those of mineral acid calculated as HCl. Taking the normal values of total acidity as lying between 40 and 60 (acidity of 100 c.cm. test meal in terms of cubic centimetres of decinormal acid) two cases gave normal and ten subnormal values, while in one a high total acidity of 77 was found. A control series of test meals was carried out on twenty children of the same class, who were in hospital convalescing from various medical conditions not of a digestive nature. In this series twelve had a complete absence of free HCl, and in four others the free HCl was below 0.1 per cent.; six gave normal and thirteen subnormal values for total acidity, while in one a high total acidity of 85 was found. One cannot, therefore, from consideration of this series, argue that the absence of free HCl, or low total acidity, in children suffering from recurrent vomiting is of any particular significance.

General Physical Signs

Several children in the series had some entirely extraneous disability, such as a rheumatic cardiac lesion. Excluding such findings there were no abnormal physical signs except what was regarded as a raised blood pressure, which was found to be present in eight of the cases under review. Raised blood pressure as a feature of some cases of the type under discussion has already been observed by Wyllie and Schlesinger.⁶ Its significance is not clear, but it may be noted, as they point out, that adults with essential hyperpiesia not infrequently give a history of migraine in early life. In thirty-seven of the cases whose urines were tested between attacks by Gerhardt's ferric chloride test, no diacetic acid was found: this is what one would expect.

Association of Headache with Vomiting

Special mention must be made of the association of headaches with these attacks of vomiting. Ophthalmic examinations to exclude errors of refraction were carried out in all cases of severe persistent headache. In no case did it appear that such errors were responsible for the attacks. It is well recognized that headache is usual at the time of such attacks, but in a number of cases the type of headache is such as to justify one in classing it as definitely migrainous. Again, certain cases under observation, which came for examination primarily because of symptoms typical of migraine (severe recurrent prostrating headache, sometimes accompanied by visual phenomena), complained of vomiting at the time of the attacks. There seems to be so close an association between these two

symptom-complexes that it is questionable whether in a number of cases they can be accurately separated. It is probable, therefore, that severe recurrent bilious attacks in childhood should be regarded as atypical manifestations of migraine.

It may be mentioned in this connexion that various observers regard migraine as being due to food allergy. Balyeat and Rinkel⁶ are of the opinion that in about 30 per cent. of all patients with migraine, symptoms have developed during the first decade of life, and that many cases of so-called cyclic vomiting may actually be cases of migraine in childhood.

Treatment and Progress

These are being discussed under one heading on account of their interrelationship.

The general lines of treatment adopted may be stated to consist essentially of:

1. The ordering of a low fat diet with liberal carbohydrates. The mother received detailed instructions regarding the types of foodstuffs to be given.
2. The prescribing of luminal, to be given at the time of attacks of severe headache, to children prominently exhibiting this symptom.

In certain cases in which a particular article of food was regarded as a possible causative factor in precipitating an attack, this was eliminated from the diet for a short period. This did not appear to make any difference, nor, in fact, did the giving of such foods seem to cause any particular upset.

One is faced with the greatest difficulty in assessing the effects of treatment and the progress of the children because of the impossibility, already mentioned, of obtaining from the mothers accounts that can be regarded as strictly reliable. Recognizing these difficulties, which are inherent in any study of this type, it is possible to make only the broadest assessment of progress in relation to treatment. Three children were not given any special dietary instructions at all. Of the remaining thirty-seven the patients were dieted for periods ranging from six weeks to twenty-one months, the average duration of the dieting being nine and a half months. Extra sugar as well as very restricted fat was ordered in most cases at the outset; later it was usual only to restrict the fats. Apart from six of the children who had no further attacks from the time of first coming under observation, there remain thirty-four cases for consideration. Of these, twenty-seven improved under dietetic treatment, and the improvement was maintained subsequently when an ordinary diet was allowed. In seventeen of these patients the improvement was regarded as very marked. Three failed to show improvement, and in two cases the improvement was doubtful. Two patients improved under dietary treatment, but regressed when given ordinary diet without fat restriction.

However great the improvement may have been, and even if no attacks were observed while the child was attending, the time of observation hardly permits one to speak of an absolute cure having been effected. There seems, however, to be little doubt that, when children suffering from recurrent vomiting attacks are ordered a diet in which the fats are much restricted, a general improvement is usually effected, and this appears to be lasting.

Summary and Conclusions

A study was made of a series of forty children suffering from recurrent attacks of vomiting, and in particular evidence was sought as to whether or not the attacks were associated with an allergic state.

There was found to be a definite family history of some allergic disorder in a considerably greater proportion of the children in this series than in a second series of

children taken as a control. Apart from this no definite evidence of allergy was found. Generally speaking, skin tests failed to reveal sensitivity to any of the common foodstuffs.

The association in childhood of recurrent vomiting attacks with migraine is emphasized and discussed. Severe vomiting attacks in childhood are probably atypical manifestations of migraine.

Treatment consisted essentially of restriction of fats in the diet. From the generally favourable progress made by these children it would appear that good results may be expected from this line of treatment in the majority of cases, and that the improvement effected is likely to continue after a normal diet has been resumed.

I should like to thank Dr. Pantton and Professor Marrack, in whose departments certain of the investigations were carried out, Dr. W. G. Bray for helpful advice, and the Research Committee of the London Hospital, who kindly assisted me with a grant.

NEW CASES OF WAR BLINDNESS DUE TO MUSTARD GAS

BY

REGINALD E. BICKERTON, D.S.O., M.B.

Ch.B., T.D.

OPHTHALMIC SURGEON, ST. DUNSTAN'S

Surprise is often expressed by the lay public, and sometimes even in medical circles, that men are still being admitted to the benefits of St. Dunstan's organization as being blinded from the results of the war. That there are many men with damage to the brain from bullet wounds, which years later have resulted in injury to the brain tissue from the effects of scarring and traction, is readily understandable; that these changes cause damage to the optic paths and optic centres, and result in blindness, more or less, is also quickly appreciated when an explanation is called for. But such explanations are comparatively rarely required, because the general public thinks that, since the war ended sixteen years ago, any after-effect of head wounds in the way of blindness would have shown itself much earlier.

Numbers of clear, well-authenticated cases of this nature are on record. In this article, however, it is not intended to touch upon these, but upon a variety of war injury which causes an immense amount of untold suffering, years of treatment, and, unfortunately, progressive loss of already much impaired vision, and the occasional loss of eyes themselves. I refer to the men who were badly gassed by shell and cloud mustard gas, and whose conjunctivae, particularly the lower fornices, are as irritable and inflamed to-day as they were after the acute effects had more or less passed off in 1917, 1918, and 1919. Very considerable oedema of the conjunctiva and lids first occurred, which slowly settled down, leaving a chronic conjunctivitis of such nature and severity that one can but conclude that some change in the tissues has taken place resulting in the loss of some lubricating secretion present in the normal eyelids and conjunctivae. This change would appear to be the total destruction of the mucin-secreting glands, a change which seems to have taken place in those distressing cases of essential shrinking of the conjunctiva and xerophthalmia.

In the latter cases, however, corneal ulceration and definite losses of corneal tissue are not a prominent feature, whereas in the gas cases, corneal destruction—thinning, ulceration, and bulging of the weakened substantia propria of the cornea—itsself is an ever-present symptom, especially the bulging and the giving way of the cornea.

I did not come across these changes in the early days of the use of gas, when lachrymatory gas, chlorine, bromine, and supposedly hydrocyanic volatiles were used, and I saw and attended the greater number of the gas cases arising during the first and second attacks in the Ypres sector. Uncomfortable and irritating as lachrymatory gas was, the effect upon the eyes and conjunctiva soon passed off, as did that of chlorine, but this latter had fatal effects upon chests, lungs, and bronchi. During these gas attacks there were no protective masks for the eyes, the only available protection being pads of gause tissue with tapes, the pad being dipped in thiosulphate of soda such as was then used in the Vermorel sprayers.

In addition to the number of cases in which the men's eyes, previously sound and normal, were directly and acutely burnt by mustard gas, and as a result the men were partly blinded, there have been many cases of old interstitial keratitis, in which the previous disability has been lighted up by the intense irritation and destruction of tissue resulting from mustard gas burning; in some instances both eyes have become affected, although the interstitial keratitis first appeared only in one eye. While it is true that the original interstitial keratitis was not in any sense a war injury, the attack following mustard gas burning was, and should be so considered. There are also cases in which, after extreme burning, some of the mustard gas became absorbed and brought about deeper changes in the eyes, such as degeneration of the retina, presumably following an inflammatory retinitis, which showed itself primarily in night-blindness. (An example of this is included later in this paper.) Such cases have been known to follow heavy doses of phosgene gas, which causes very few local and immediate symptoms, but deadly after-effects; not many have followed mustard gas burning.

Case Notes

The men in the following cases have all come to St. Dunstan's for admission or assistance owing to their wretchedly uncomfortable eye conditions, with progressive deterioration of vision in spite of continuous treatment. Most have lost their jobs through failing vision, and some are unemployable because of the appearance of their eyes, the uncertainty of being able to carry out any work without continual breakdowns for treatment, and, sad to relate, the objection of fellow workers. They have all come up within the last eighteen months.

Case 1.—The patient, aged 38, was seen on July 12th, 1934. He was wounded on the Somme, was in hospital six months, and was then sent back to a Pioneer Battalion. He was gassed in 1918 (mustard gas), and, as a result, spent nine months in hospital. His chest was affected. He began to lose his sight after being gassed, and it was for this that his pension was granted. Vision R., largest letter at one foot indefinitely. Vision L., largest letter at six inches indefinitely. Field of vision very contracted. This man was a sniper for two years after going on foreign service. Fundus shows marked retinal degeneration and pigmentation. Cornea and conjunctiva not markedly affected.

Case 2.—Patient, aged 50, seen in April, 1933. As a result of mustard gas poisoning at St. Quentin in August, 1918, he was invalided out, and in hospital from August to November. His eyes have given trouble ever since, and broke down finally in February, 1929. He has been under continuous treatment since he was gassed. Left eyelids have been stitched up since July 15th, 1932, and are still closed. Right partly stitched in September, 1932, and remains so. Vision R. less than 1/60; vision L. still less. Both conjunctivae, when

seen, were considerably congested; right, roughened and discharging; left, cornea still ulcerated. The man is quite unable to get work or to perform it, and is being trained as a blind man. He is under treatment at the Ministry of Pensions Hospital.

Case 3.—This patient, aged 44, who was seen on June 7th, 1934, was gassed by shell at Ypres on September 27th, 1917. He spent seven months in hospital, and has been under treatment ever since. Vision R., 3/60 just; vision L., largest letter at one foot. Right: corneal nebula, opacities on lens capsule, signs of iritis; tension normal, no view of fundus. Left: scarred cornea, raised patches with clear cornea between; eye tender and cannot stand daylight. Eyes and vision have deteriorated lately. He left the Ministry of Pensions Hospital, where he had been an in-patient, just before Whitsuntide of this year. He has been under treatment ever since being gassed, and had to give up his own business on January 26th, 1934. His chest is also giving trouble.

Case 4.—The patient, aged 37, was seen on June 7th, 1934. He was gassed near Albert in 1918, and was in hospital as a result for six weeks, during which time his eyes were completely closed, and he was unable to open them for two weeks. Ulceration continued. Nebulae in lower half of right, and a very dense leucoma down and out in lower half of left cornea. Vision R., 4/60 indefinitely; L., 1/60. Eyes have been inflamed again this year. In this case the gas shell burst in the entrance of a tunnel, in which the man was working a signalling lamp; he thus had the full benefit of the mustard fumes.

Case 5.—A gunner, aged 44, seen in February, 1931, was gassed at Armentières in 1918. Right eye: no perception of light; tension minus; cornea opaque and disintegrated in lower two-thirds, bulging and perforated; anterior chamber collapsed. Iris adherent to wound. Left eye: perception of light, but cannot count fingers. Lower half of cornea opaque and roughened, lens capsule opaque, pupil bound down. This man's body, wherever there was moisture—armpits, thighs, etc.—also burned at the same time.

Case 6.—This patient, who was gassed in France in 1918, was seen on July 26th, 1934. He had never had any comfort with his eyes since he was gassed, nor did he do any further service. His eyes very badly ulcerated; left stitched up for a year. He never goes longer than six weeks without having exacerbation, and has extensive calcareous deposits in both corneae. His own doctor has treated him for his eyes for nine years. Vision R., 2/60 barely; L. less than this. Both corneae hazy, due to dense infiltration masking the whole cornea.

Case 7.—Patient seen on July 26th, 1934. He was gassed (cloud gas) at Villars in 1918, and, as a result, was in hospital from May to December, 1918. Both corneae badly burned; nebulae, calcareous film right; has been under treatment ever since being gassed, and was in a Ministry of Pensions Hospital from 1930 to 1931. Right vision: sees light only—or thinks he does; left vision: 1/60 eccentrically with head held very much on one side. Vision is still deteriorating.

These authenticated cases are sufficient to prove that much acute suffering is still being uncomplainingly borne, and all such cases will eventually be cared for by St. Dunstan's organization, and account for the recent admissions.

The first number has appeared of a new journal, *Acta Cancerologica*, published in Budapest under the general editorship of Dr. Paul Geré. The articles are printed in English or French or German, at the author's choice, each being followed by a summary in all three languages. Publication will continue at intervals of one and two months, the annual set of twelve single or six double copies being bound in one volume. The English agents are Messrs. H. K. Lewis and Co. Ltd., 136, Gower Street, W.C.1, who will be pleased to send particulars of the journal to inquirers. The subscription is £4 for one year, and £2 2s. 6d. for six months.

Clinical Memoranda

NON-FATAL LIGHTNING BURNS

It has long been a canon of surgical practice that "if one-half the superficial area of the body of an adult is burnt, no matter of what degree the burn is, or one-third of the body of a child, the burn will end fatally."¹ Again, "involvement of one-third of the skin surface is a very grave matter and, if this includes the abdomen, the outlook is practically hopeless."² The following case, which occurred in August, 1933, is recorded both for the interesting clinical features and for the unusual satisfactory result.

CASE RECORD

One evening, during a thunderstorm, two boys, aged 12 and 7, were about to enter a cowshed in order to milk several cows when the building was struck by lightning. The cow nearest to the door was killed instantly. (Subsequent examination by a veterinary surgeon showed no detectable abnormality.) The boys were thrown down and rendered unconscious.

The younger of the two was hurled several yards away from his brother. Apart from shock his injuries were slight. A certain degree of cerebral irritation supervened the following day; after a few days' complete rest in bed he made an uninterrupted recovery. It is interesting to note that, of the two, the younger boy showed a far greater degree of psychological sequelae, in the form of "terror-dreams," and during a thunderstorm all the signs of extreme fear, including, on a recent occasion, a temporary paresis of both legs and incontinence of urine lasting twenty-four hours.

The older boy, who was carrying a galvanized bucket in his left hand, was severely burnt. It would appear that the lightning "earthed" itself through the bucket. The burns extended all over the back, from the nape of the neck to the fold of the nates on both sides: down the left leg to the ankle; over the front of the thorax from the suprasternal notch to the xiphisternum, extending across the abdomen from the right iliac crest to become continuous with those on the back. The only free portion of the trunk was an area from the right axilla, two inches broad, down to the lower border of the ribs, and broadening an inch to the level of the umbilicus.

The left arm was charred black from the shoulder to the elbow; the muscle fibres of the biceps could be seen clearly. The fingers of the left hand, on the dorsal surface, were scarcely affected; the palmar surface was burnt to the second degree. In the earlier stages of recovery it appeared as if a permanent state of contraction of the fingers would result, independently of the healing of the flesh. Subsequent events have shown that this was probably a functional contracture of psychological origin and not due to any local or neurological damage. The head, right arm, and leg escaped injury. It was in the right hand that he had held a wooden milking-stool. The latter was found, without its legs, at the other side of the shed.

The patient was seen about twenty minutes after the accident. He was then unconscious, breathing stertorously, and the skin cold and clammy. The pupils were dilated. He had been totally incontinent. He was practically naked; the cuffs of his shirt, held by metal buttons (which were twisted), were all that remained of his upper garments. There were no arborescent markings on the skin such as have been described by some observers.

RESPONSE TO TREATMENT

Consciousness returned in three to four hours. The wounds were cleansed gently by allowing a solution of 1 in 1,000 mercury perchloride to flow over the surface. Later, these were sprayed with colloidal tannic acid solution (2½ per cent.). This was repeated at hourly intervals. Because of the ex-

tensive nature of the wounds, a 5 per cent. tannic acid ointment dressing on broad sheets of lint was substituted the next day, and changed daily during the following three weeks. Thereafter the intervals between changing the dressing were gradually increased. The last "black crust" separated at the end of the eighth week. From this time a 1 in 1,000 solution of acriflavine emulsion replaced the tannic acid dressing. There was very little sepsis except from the wounds on the abdomen. The temperature rose to 102° on the second day, and remained above normal constantly during the first three weeks. The pulse rate gradually increased out of proportion to the temperature and the heart-muscle sounds became progressively of poorer quality, probably due to a degree of myocarditis. A Nativele granule grain 1/600 was given morning and evening for three months with no ill effects. The rhythm remained regular throughout.

No morphine was given during the period of shock. Contrary to the usual advice, strychnine sulphate grain 1/100 was given every four hours for the first week. Glucose drinks and glucose salines per rectum were administered at four-hourly intervals during the period of shock. On no occasion was it necessary to use an anaesthetic to allay the pain during the dressing of the wounds.

Permission for skin grafting was not obtainable. The only stimulating treatment available for the wounds was that afforded by the actual rays of the sun, and the scarlet red ointment of the *National Formulary*. The effect of the ointment was remarkable in producing a rapid epithelialization when it was applied around the circumference of the wounds and covered by lint soaked liberally in acriflavine emulsion.

The total time taken for complete healing was ten months. It is characteristic of electric burns that they heal slowly. Apart from those mentioned above there were no complications, and recovery has been uneventful. "Halimalt" and a simple mixture of glycerophosphates were given during convalescence.

The ultimate results are, on the whole, satisfactory. The boy now has the complete use of his hands, and, apart from a certain amount of contracture at the left shoulder region, there is every likelihood that, in time, he will become a useful agricultural worker.

E. GRAHAM ELWELL, M.B., Ch.B.

High Bickington, Devon.

AN UNUSUAL LARYNGEAL FOREIGN BODY

The following instance of impaction of a foreign body in the larynx is, I think, of sufficient interest to be worth recording.

A child, aged 10 years, was admitted to hospital an hour after having swallowed an unusual type of foreign body—namely, the "eye" component of a "hook and eye" appliance for joining dress material. The child had apparently been playing with the foreign body, when it was noticed to have a sudden spasm of choking and become hoarse. An x-ray revealed the foreign body at about the level of the pharyngeal pyriform sinuses, a little to the left of the middle line, with its longitudinal axis in the sagittal plane, and the "eye" component directed posteriorly. Direct laryngoscopy two hours later, under general anaesthesia, revealed the foreign body lying as to one-half over the anterior part of the left vocal cord and the remaining half below the left cord in the subglottic region, with the "eye" of the appliance directed towards the middle line. The slit in the horizontal limb had passed over the free margin of the true cord, so that the foreign body was encircling the true cord. When the position and relation of the foreign body had been appreciated, extraction with the forceps through the laryngoscope presented no difficulty. The foreign body was grasped by the forceps at the upper limb of the "eye," and gentle upper traction applied.

Manchester.

BRAIN ABSCESS

Elaboration of the Jacksonian prize essay for 1926 has resulted in a volume on *Abscess of the Brain*, by Mr. E. MILES ATKINSON.¹ The monograph is based upon twenty-three cases of brain abscess treated or personally observed by the author. All save one were of aural origin, and with one exception all were temporo-sphenoidal or cerebellar in situation. The series is admittedly rather small, and to supplement this and provide a complement of cases of different origin the author has drawn upon a wide field of literature, and provides an excellent bibliography. The anatomy and pathology of brain abscess are dealt with admirably in a comprehensive fashion. The author's own researches make him of the opinion that the spread of infection into the brain substance is by the perivascular route in a great majority of cases and less frequently by the process of retrograde thrombophlebitis, which is more favoured by transatlantic writers.

A full account of the general and local signs of brain abscess is given. Mr. Atkinson rightly emphasizes the necessity of repeated examination for the detection of transient localizing signs, and stresses the danger, which ought to be more widely appreciated, of allowing more than one or two cubic centimetres of cerebro-spinal fluid to escape on performing diagnostic lumbar puncture. But it is doubtful if the cerebro-spinal fluid can be estimated even approximately without a manometer, as he maintains, and surely the manometer is the best check against too much loss of fluid. His statement that tests of visual fields have proved of no value to him will surely be amended in the future.

Mr. Atkinson's opinion that operation, or at least exploratory puncture, should be performed just as soon as the diagnosis of brain abscess is made, whether localizing symptoms are present or absent, will, as he expects, be contested by many. In spite of his agreement with others that Macewen's unsurpassed results were probably due to the long-standing nature of his cases before operation, and in spite of several recent papers advocating delay as long as possible, he maintains that the risks of such procedure are too great. It is difficult to understand such compelling dogmatism based on limited experience. The various methods of approach and drainage used by different writers—*quot homines, tot sententiae*—are fully dealt with. The author himself favours a double tube for drainage and irrigation.

The monograph is well produced and illustrated. If it lacks conciseness, that is probably due to the zeal of the author for his own personal contentions making his style a little reiterative.

ORTHOPAEDIC SURGERY

Dr. GEORG HOHMANN's book on Foot and Leg, their Disorders and the Treatment of Them, appeared first in 1923. A second and enlarged edition, with many more illustrations, has now been published.² The title "Foot and Leg" suggests, to English eyes and ears, that the book deals with the surgery of the whole lower extremity, but that is not in fact the case. Dr. Hohmann is director of the University Orthopaedic Clinic of Frankfurt-on-Main, and he confines himself in this book almost entirely to deformities and to orthopaedic methods of treatment. He leaves out such maladies as tuberculous joint disease and

osteomyelitis. While he describes and discusses various congenital deformities he omits club-foot, but includes, on principles of selection which seem obscure, chronic varicose ulcer of the leg.

In his preface the author points out that during the past decade there have been notable advances in the field of orthopaedic surgery, and that this volume is not simply a revision and amplification of the first edition, but an entirely new work, the outcome of thirty years' work on the foot and experience of thousands of patients with foot maladies. Several new chapters have been added on maldevelopment of the foot and toes, which are of practical importance, such as those on the processus trochlearis, on the sesamoid bones, and athletic injuries, especially those of the joints of the foot and ankle. The author is a follower of Max Lange, whose monograph on myogelosis, or muscle induration, we noticed nearly four years ago. (See *British Medical Journal*, 1931, ii, 536.)

The book is written, he says, for the orthopaedic specialist as well as for the general practitioner. Within the limitations aforementioned *Fuss und Bein* should be found useful to those seeking information about deformities of the feet. The numerous illustrations are clear and informative. The value of the book as a work of reference is seriously diminished by the absence of an index, which is the more felt because the table of contents is very laconic.

SERUM DIAGNOSIS OF GONORRHOEA

Serum Reactions in Gonorrhoea,³ by BERTRAND RÈME, is a valuable addition to medical literature for a number of reasons. It gives a historical review of the evolution of the complement-fixation reaction in gonorrhoea from its commencement in 1906; the technique, taking reagent by reagent; its interpretation, sensitiveness, and specificity; and finally a most comprehensive bibliography.

Müller and Oppenheim are given the credit of being the first to apply, in 1906, the principles of Wassermann and Bruck to the serology of gonorrhoea. From that date numerous workers—all mentioned by name—have gradually evolved a test which to-day may be considered to be as valuable in gonorrhoea as the Wassermann reaction is in syphilis. A long and interesting section on the history of the complement-fixation reaction is followed by one on technique; as regards the patient's serum, complement, and haemolytic system most workers are in general agreement—it is over the question of antigen that methods differ widely. In general, antigens may be divided roughly into those treated by physical and those by chemical means. The former include emulsions and filtrates, whilst the latter comprise those made by extraction with alcohol or ether or solution in soda or antiformin. A comprehensive table is given of the various types of antigen employed, together with the names of the workers who use them. As regards specificity, the question of cross-fixation with the meningococcus and *Micrococcus catarrhalis* arises. There seems to be a general consensus of opinion that this does take place: with the former it is not usually of much importance, since the differential diagnosis is easy, but in the case of the latter difficulties may arise. It appears possible that the solution may lie in testing the serum in question against antigens made from each kind of organism. Much more work, however, requires to be done on this question. The bogy of cross-fixation with a syphilitic serum is finally laid—it should never occur with a good technique. The complement-fixation reaction will stand comparison with other laboratory methods in the diagnosis of gonorrhoea: excluding early acute cases, far more positive results are obtained with it than with films or cultures.

¹ *Abscess of the Brain: Its Pathology, Diagnosis and Treatment*. By E. Miles Atkinson, M.B., B.S., F.R.C.S. London: Publications, Ltd. 1934. (Pp. 289; 45 figures. 21s net.)
² *Fuss und Bein. Ihre Erkrankungen und deren Behandlung*. By Professor Dr. med. Georg Hohmann. Second edition. Munich: J. F. Bergmann 1934. (Pp. 380; 326 figures. R.M. 24; geb. R.M. 25 80.)
³ *La Seroreaction Blennorrhagique*. Par Bertrand Rème. Paris: Masson et Cie 1934. (Pp. 179 20 fr.)

On the question of sensitiveness most workers agree that the test is usually positive: (1) after about the second week, (2) in nearly all complications such as arthritis, and (3) where there is a closed focus of infection. Opinions differ as to how long the reaction remains positive after cure, and what importance must be attached to a persistent positive remaining long after all signs have disappeared. Speaking generally, the reaction may be expected to return to negative in from six to twelve weeks following cure: where a strongly positive reaction persists the inference is that a focus of infection exists somewhere and must be sought for diligently; cases which have suffered from complications often show a positive reaction for months or even years after all symptoms have disappeared, and may perhaps be considered on a par with "Wassermann-fast" syphilitics.

This book is essentially a digest of all the work that has been done on the subject, no author of any note being omitted. The various methods are described and the opinions of the various workers quoted. The reader is left, very largely, to decide for himself which are the better techniques and to draw his own conclusions, though here and there the author gives his own views and experiences. All who have to do with the management of gonorrhoea should read this valuable work; if its publication succeeds in stimulating further interest in a subject which has not received the attention it deserves Dr. Rème will be in some degree compensated for undertaking a most laborious task. There can be little doubt that the value of the reaction is well established, and those who treat gonorrhoea without its aid are handicapping themselves severely: it is a curious fact that those who tend to belittle the value of the reaction are those who have least experience of it.

THE B.C.G. VACCINE

Dr. K. NEVILLE IRVINE, during his recent tenure of the Radcliffe Travelling Fellowship, spent two years visiting clinics and laboratories in Europe and America in order to collect data on the method of vaccination against tuberculosis introduced by the late Professor Calmette. His findings are incorporated in a short book entitled *The B.C.G. Vaccine*.⁴ In this work Dr. Irvine deals with the main questions that have excited discussion among scientific workers. His method is to devote a separate chapter to each question, to review briefly but comprehensively the published reports on the subject, to mention sometimes the work under progress, and, after a critical assessment of the findings, to furnish a fairly definite answer to the question posed at the commencement. As a result Dr. Irvine concludes that (1) the B.C.G. is not a "virus fixé," but can (or could until recently) increase in virulence when cultivated under suitable conditions; the parenthesis is necessary because the B.C.G. has shown signs lately of decreasing still further in virulence; (2) the B.C.G. does occasionally produce progressive tuberculosis in laboratory animals, though it has never yet been definitely proved to have done so in man; (3) a definite degree of immunity can be produced in cattle by B.C.G., though in other animals the results are doubtful; (4) a certain undefined degree of immunity can be produced in man by the vaccine; and (5) the vaccine should be given to children in tuberculous families to supplement the existing measures of control.

These views are very similar to those which have been advanced in the editorial columns of the *British Medical Journal* during the past few years, and are likely to meet with a considerable measure of approval. The real crux

of the matter is how great and how lasting is the degree of immunity produced. At present the evidence does not suggest that it is either great or of long duration, so that the general application of the vaccine is out of the question in this country. Its use must therefore be restricted to specially exposed classes. Since these constitute but a small fraction of the total population, information on the value of the vaccine will be very difficult to obtain unless a properly organized programme is laid down and adhered to by such bodies as the Ministry of Health and the Medical Research Council acting jointly.

Dr. Irvine is anxious that research on man should be undertaken, and is fully aware of the statistical fallacies that have marred so much of the work carried out in other countries. His book, by providing a reasoned résumé of the highly controversial data on B.C.G., will not only attract a wide public, but may lead to a demand for more exact knowledge of the protective value of the B.C.G. vaccine.

CORRECTIVE PHYSICAL EDUCATION

In her book with this title⁵ JOSEPHINE LANGWORTHY RATHBONE has made a conscientious attempt to produce a sound textbook for students of physical education to enable them to help the child who is suffering from faulty development or definite deformity, or who is otherwise maladjusted to take his part in the activities of normal life. Having reviewed the anatomy and physiology necessary for the understanding of normal body mechanics, the author describes the commoner types of faulty development and orthopaedic lesions, and explains how physical therapy may correct or help to compensate for these handicaps. She lays stress upon the importance of psychological factors in reconstructive work, and discusses the need for co-operation between home and school if corrective physical education is to have a reasonable hope of success. Systems of general exercises are given, and special exercises for different regions of the body. These are illustrated by "stick-man" diagrams, which show movements clearly, but, being small and spidery, are rather irritating in the text. A bibliography is appended; and a glossary in which the choice of words is curious. Why waste space in defining words in common use, such as "sleep," "normal," "obesity," "rigidity," "true," and give so little enlightenment about a word like "bacillus," which is merely mentioned as "a rod-shaped body"? The author does not claim to have contributed any original material to her subject, but she has its advancement very much at heart, and here presents her own knowledge and experience in such a way as to make it of practical benefit to students of physical education.

CHEMISTRY OF THE HORMONES

The Chemistry of the Hormones,⁶ by Professor B. HARROW and Dr. C. P. SHERWIN, is a useful monograph that summarizes current knowledge on this subject. It is divided into nine chapters, which deal with the following matters: thyroid and parathyroid hormones, insulin, pituitary, adrenal, male and female hormones, secretin, and plant hormones. The greater part of the volume is concerned with the methods used to isolate hormones from glands and other tissues. Adequate accounts are also given of the chemical properties of the hormones and our knowledge regarding their chemical structure, together with short accounts of the biological tests used

⁴ *Corrective Physical Education*. By Josephine Langworthy Rathbone, M.A. Philadelphia and London: W. B. Saunders Company, 1934. (Pp. 222; 153 figures, 12s.)

⁶ *The Chemistry of the Hormones*. By Benjamin Harrow, Ph.D., and Carl P. Sherwin, D.Sc., M.D., D.P.H. London: Baillière, Tindall and Cox, 1934. (Pp. vii + 227. 1s. 6d.)

⁴ *The B.C.G. Vaccine*. By K. Neville Irvine, D.M., M.A., B.Sc. London: H. Milford, Oxford University Press, 1934. (Pp. 70. 5s. net.)

in the estimation of hormones. A selected list of references appears at the end of each chapter.

The introduction of a short chapter on plant hormones deserves special notice, for the authors here discuss the chemistry and actions of the remarkable substance auxin, discovered by Kögl and his associates in Utrecht about two years ago. Auxin controls the growth of growing plants, and is of interest because of the extraordinary intensity of its action. A measurable response is produced by one fifty-millionth of a milligram. Mention also is made of tokokin, the substance allied to oestrin which Butenandt has isolated from plants. These discoveries promise to throw new light on the comparative physiology of hormone formation.

We think that *The Chemistry of the Hormones* will be found more suitable for reference than for general reading. The subject is one that is changing every month, and the prime necessity of a monograph of this kind is that it should provide a reliable summary of the most recent work. This purpose the monograph under review fulfils excellently.

Notes on Books

Dr. H. L. Tidy's *Synopsis*⁷ has established a place among the textbooks of medicine. The sixth edition, revised and enlarged, remains a handy volume of 1,100 pages, packed with information. Since the last edition, reviewed in our columns at the end of 1930, many advances have been made in medical knowledge, and the author has rewritten and brought up to date the sections on anaemia, nephritis, diseases of the endocrine glands, and deficiency disease. In these, as in other parts of the book, we are pleased to meet again the lucidity and crispness of style found in former editions. The author in his original preface suggested that the synopsis should not be used by students to replace a textbook of medicine; but it has a distinct role where revision of all the essential material is required by students or teachers, and consultants who carry "Tidy" with them on their rounds will find it a never-failing source of accurate information. A full index of over fifty pages enables any subject to be readily found. The new edition worthily maintains the high standard of former ones, and should meet with the same success.

The eighth volume of the *Transactions of the Bose Research Institute, Calcutta*, contains further observations by Sir CHUNDER BOSE on the movements and growth of plants.⁸ He had already shown that in sensitive plants the conducting tissues transmit impulses in a manner analogous to nerve impulses in animals; his latest researches establish the generalization that the motor mechanism is essentially similar in ordinary plants also. A second paper by Sir Chunder Bose bears on the problem of eliminating a voracious fish (bhетки), which is often present and does great damage in tanks used for stocking edible fish. He has discovered a vegetable extract which, in very dilute solutions, kills the bhетки without injuring the edible fish. An interesting paper by Mr. N. C. NAG contains observations on the influence of manganese in plants, in relation, more especially, to the inflorescence and to the proper functioning of green leaves. Mr. P. C. BASU contributes a paper on the racial affinities of the Mundas, one of the aboriginal tribes, which still retains its native purity of blood. Anthropometric details and cranial measurements are given, and the paper is illustrated with excellent photographs of the various forms of head and cranium met with in these natives. Other articles relate to variations in the growth of the stem and

roots of plants, the effect of certain Indian drugs on the peristaltic activities of animals, the composition of oils from leguminous plants, and the absorption-spectra of the vapour of silver and lead haloids.
